There has been brought before the Council of the British Association at the Toronto meeting a special report by the Committee on Zoological Bibliography nd Publication, dealing with the question of undue estriction in the distribution of H.M. Government ublications. The results of the inquiries of this Com- ittee are of general interest to scientific workers, and ay be briefly stated. On applying to the heads of ertain Government Institutions, the Committee was nformed that no restriction had recently been placed n the distribution of publications of the Royal otanic Gardens, Kew, the British Museum (Natural istory), or H.M. Geological Survey. On the other and, it found that public libraries had suffered from considerable cutting down of free or reasonably riced Parliamentary and Stationery Office publica- ons (in respect of which some concession has since een made); that certain British scientific societies f standing are no longer able to obtain Government cientific publications in exchange for their own ublications (though foreign scientific societies are not milarly handicapped); that free reprints to authors f papers published by the Government have almost isappeared; that there has been a cessation of the outine free distribution of agricultural leaflets; and hat review copies of Government publications have een curtailed. These findings are in general agree- ent with the statements made in a leading article n Nature, December 29, 1923 (vol. cxii. p. 925). he Committee considers that no loss would ensue ere review copies to be furnished gratis to editors on pplication, and suggests that the Council of the British Association "might well represent to the Government that the publication of the results of esearch among people likely to appreciate them is no ess important than the making of the researches hemselves, and that to refuse the relatively small dditional expenditure is materially to reduce the enefit of the original much greater expenditure." Bearing in mind the effective methods employed by ther governments in the spread of their scientific chievements, no one is likely to quarrel with this xceedingly modest recommendation.

Scientific men are indebted to Major A. G. Church or raising an important question in Parliament, namely, the assessment for income tax of professional men, more especially men of science, who are remunerated by a fixed salary and are therefore assessed under Schedule E. Professional men whose income is made up of fees, and who are, therefore, assessed under Schedule D, are allowed in the assessment of their incomes to deduct from their earnings expenses ordinarily incurred in the course of their work, including the cost of the renewal of technical works of reference, subscriptions to professional societies, the preparation and publication of memoirs —in fact, all expenditure required to maintain their technical efficiency. Such expenses are not as a rule allowed to those assessed under Schedule E. The Financial Secretary to the Treasury denied, however, the existence of such a distinction and offered to have any particular case investigated, in which further relief was believed to be due, provided the necessary particulars were furnished. The question was, as a matter of fact, brought before the Treasury two or three years ago, when it was intimated that such expenses might, for the purpose of assessment, be deducted from the salary received, when they were incurred in consequence of an express requirement of the employer. If, for example, on the appointment of a science lecturer it was stipulated he should carry out research, or that he should join the technical societies relevant to the subject he taught, or take other steps calculated to maintain his scientific position, the necessary expenses might be deducted in ascertaining his assessable income. It is for the colleges concerned to see that this requirement is satisfied.

The Admiralty has announced the appointment of Capt. H. P. Douglas to the post of Hydrographer of the Navy in succession to Vice-Admiral F. C. Learmonth, as from October 1 next. Capt. Douglas has been employed in the surveying branch of the Navy since 1897, and held the appointment of superintendent of charts in the hydrographic department from 1910 to 1914. During the War, he was employed on special surveying staff duties at the Dardanelles and with the Dover Patrol, in addition to acting as the first director of the Navy Meteorological Service (1917). For his preparatory work in connexion with the raid on Zeebrugge he was awarded the C.M.G. He was assistant hydrographer of the Navy from 1919 to 1921, and has since been in command of H.M. Surveying Ship *Mutine*, and her successor,

H.M.S. *Ormonde*, on the Bermuda and West Atlantic Survey. He is the inventor of several instruments and diagrams for use in surveying and navigation. The post of Hydrographer of the Navy (instituted in 1795) was originally tenable at their lordships' pleasure, and for an unspecified term. Admiral Beaufort, still remembered in connexion with the "Beaufort scale" of wind velocities, occupied the position for twenty-six years (1829–1855), and the late Rear-Admiral Sir William Wharton for twenty (1884–1904). Since the latter's time, however, the tenure of the post has been limited to five years, its successive occupants having been Admiral Sir A. Mostyn Field (1904–1909), Admiral Sir H. E. Purey-Cust (1909–1914), Vice-Admiral Sir J. F. Parry (1914–1919), whose grandfather, Sir W. E. Parry, the celebrated Arctic explorer, was Hydrographer in 1823–1829 and the present Hydrographer, Vice-Admiral F. C. Learmonth, who, before taking up his appointment as Hydrographer, was Director of Fixed Defences from 1914 to 1919, and in that capacity won unstinted praise from Lord Jellicoe for his work in the production of net defences, both for the British fleet and for those of the allies.

THE Council of the National Institute of Agricultural Botany announces that it proposes to place upon the market this autumn about 2500 quarters of a new seed wheat, Yeoman II., bred by Prof. R. H. Biffen; and tenders as to quantity are invited from established dealers in seed corn. The seed wheat will be sent out in sacks closed with the Institute's seal, none other being genuine, at the rate of 6*l.* 6*s.* per $4\frac{1}{2}$ cwt. Yeoman II. is intended to take the place of the older Yeoman wheat, partly because pure seed of the latter is now difficult to obtain owing to admixture with other wheat, partly because Yeoman II. is a better wheat in several respects. Both wheats are products of the same cross, Browick × Red Fife, and are similar in type. The yielding capacity of Yeoman II. has been tested out at ten different centres on varying soils throughout the country, with thoroughly satisfactory results. Comprehensive milling and baking trials made by impartial judges of the National Association of British and Irish Millers indicate that the bread made from the flour of Yeoman II. is of exceptionally good quality and is "incomparably superior to anything obtainable from average ordinary English wheat." In favourable seasons the loaves approximate closely to those from "No. 1 Manitoba" wheat. It is strongly advocated that from the different points of view of growers, millers, and consumers, Yeoman II. should take the place of the older form. It is particularly suitable for growing on medium and heavy soils which are in good heart, and is specially recommended for the eastern, midland, and southern counties of England, the best results being obtained with early sowing.

A TALK on "Life of the Sea-shore," by Mr. T. Howard Rogers, broadcast from the Birmingham Station of the British Broadcasting Co. on July 29, was the first of a series which will be continued until the end of the year by members of the Birmingham Natural History and Philosophical Society. On August 9, Mr. O. T. Elliott dealt with "Germs Beneficial and Otherwise," and the second and concluding part of his lecture will be given on August 1. Other talks which have been arranged are: "Butterflies," by Mr. J. H. Grant (Sept. 9); "The Earlier Known Life of the Earth," by Mr. Frank Raw (Sept. 17); "Flies," by Mr. Colbran J. Wainwright (Sept. 23); "Fossils," by Dr. L. J. Wills (Oct. 7); "How we get our Time," and "The Moon," by the Rev. T. S. Phillips (Oct. 14); "Plant-animals," by Dr. W. Elliott (Oct. 21); "Fairy Rings," by Dr. Jessie Bayliss Elliott (Oct. 28); "Algeria," by Capt. K. Shepherd (Nov. 4); "Shells," by Mr. H. Overton (Nov. 11); "Life of the Ocean," by Mr. T. Howard Rogers (Nov. 18); "Saturn," by Mr. S. C. Paris (Nov. 25); "Aquaria," by Mr. G. T. Calvert (Dec. 2); "The Modern School-boy," by Mr. F. W. Pilditch (Dec. 9); and "The Life-story of the Eel" by Dr. A. J. Grove (Dec. 30). The subjects are being dealt with in an interesting and non-technical manner; and it is hoped that these instructive talks which are addressed primarily to young people, will arouse interest in, and foster a taste for, natural history and kindred scientific subjects, and prove a helpful contribution to the valuable educational side of the programmes broadcast by the B.B.C.

IN connexion with the Exhibit in Gallery II. of the Government Pavilion at Wembley, by the Cambridge School of Agriculture, illustrating fertility and sterility in domestic animals, an excellent explanatory memorandum by Mr. J. Hammond has been issued by the Ministry of Agriculture and Fisheries. Sterility in the male is illustrated by microscopic preparations showing the semen of a sterile bull devoid of spermatozoa owing to the atrophy of the seminiferous cells —a condition which may follow inbreeding and other types of mismanagement. The reproductive process in the female is illustrated by a preparation of the reproductive organs of the cow, and the memorandum gives a short but clear summary of what is known of the physiology of these organs. Incidentally, mention is made of the striking demonstration of the control exercised by the corpus luteum over the ripening of the next Graafian follicle, that is obtained by expelling the corpus luteum from the ovary by simple pressure through the rectal wall, the result of this operative procedure being to bring on the next heat period before the time at which it would normally occur. Various causes of sterility in the cow are dealt with in the memorandum. The exhibit dealing with the sow illustrates the curious secondary limitation of fertility which occurs in this animal through degeneration and elimination of some of the embryos during the period of pregnancy, the potential brood of about 20 being reduced in this way to an average of about 8 or 9. In the rabbit such absorption of fœtuses is produced experimentally by removal of corpora lutea during early pregnancy, but in this case all the fœtuses disappear instead of only some of them as is the case in the sow. A similar result is seen in a rabbit which mates while still suckling a large litter, very active lactation having itself a

atrophic influence on the corpora lutea: in this case the effect may be prevented either by reducing the number in the litter to one or two, or by special feeding. The exhibit is one of much interest, and it will serve a good purpose by directing attention to the enlightened policy adopted by the Government of recent years, of encouraging research in external institutions such as Universities and independent laboratories.

Mitteilungen, No. 6, for June 1924, of the Society of German Men of Science and Physicians, are largely occupied by a discussion of the participation of Germany in international congresses. Léon Bourgeois is quoted as having said in 1913: "Coordonnons nos recherches, unissons et centralisons nos efforts, ne nous laissons distraire ni diviser par rien . . ." That was in the earlier days of tuberculosis inquiry, to which Koch, Ehrlich, and Behring have since contributed. Fritz Haber has spoken explicitly as president of the German Chemical Society meeting on May 12. He notes a mellowing of relations and a wish for closer scientific intercourse, expressed in particular by the United States, England, Russia, and Japan, as, for example, the invitations of the British Chemical Manufacturers and of the World Power Conference. The facts are given in greater detail in a paper on "International Scientific and Technical Congresses," pp. 53 to 67 of *Mitteilungen des Verbandes der Deutschen Hochschulen*, May 1924. The editor invites further reports directed to Johannisstr. 7, Münster in Westphalia. A list of 84 congresses is reviewed. Germans have joined in discussing physiology at Edinburgh, psychology at Oxford, orthopedics at Amsterdam, plant diseases at Wagening, serum at Copenhagen, pedagogy at Montreux, international law at Brussels, psychic sciences at Warsaw, dentistry in Paris, meteorology at Utrecht, gardening at Amsterdam, sociology in Rome, milk at Washington, philosophy in Naples, applied mechanics in Delft. Co-operation is absolutely necessary for the future of science, but much patience is required, for pressure in any direction might hinder more than help. The fullest list of international societies of all sorts is the "Répertoire des Organisations Internationales," published in Geneva for the Société des Nations. The director, Section of International Bureaux, League of Nations Secretariat, asks for information as to new societies or changes in older ones.

PROF. DR. RICHARD ZSIGMONDY, of Göttingen, has been elected a corresponding member of the Vienna Academy of Sciences.

A PROFESSOR of science is required at the Royal Military Academy, Woolwich, particulars of which can be obtained by written application from the Under Secretary of State, War Office (S.D.3), Whitehall, S.W.1. The completed form must be returned by August 21.

THE Department of Scientific and Industrial Research invites applications for the post of superintendent of its Chemical Research Laboratory. Candidates should have had experience of, and be distinguished in, some branch of pure or applied chemistry. Particulars of the duties of the post and a form of application are obtainable from the secretary of the department, 16 Old Queen Street, S.W.1. The latest date for the receipt of applications is September 30.

A SHORT time ago the question was raised in NATURE as to the possibility of registering priority in scientific discovery, on the analogy of a patent registering priority in invention. The device of sending in contributions under seal need not be forgotten. Even if afterwards published in some more finished form, the sealed documents should afford proof of the stage already reached at the date when they were handed in. The Academy of Sciences in Vienna reports the receipt of papers on the reproduction of lantern slides by an electrical method, on the action of Röntgen rays on organism, and a new treatment of carcinoma, a proof that the equation $x^n+y^n=z^n$ has no solution in rational numbers when n is greater than 2, and several other matters.

WE have received from the Russian Academy of Science of Leningrad the June issue of *Electritchestvo*. In honour of the centenary of Lord Kelvin it is called the "Lord Kelvin Number," and is devoted to articles in appreciation of his various activities by eminent men of science and engineers. The address presented at the Commemoration Celebration in London is quoted. "All Russian scientific men and engineers send their greetings to the Mother Country" of Lord Kelvin. "May the same spirit of sincere fellowship, which unites to-day the scientific workers of the whole world, form closer bonds between them for the benefit of humanity." Prof. Steklov, the vice-president of the Russian Academy of Science, writes an appreciation of the wonderful creative genius of Kelvin and his constant searchings after new physical laws. He, more than any one, tightened the bonds between pure science and engineering. Prof. Ossadchy, vice-president of the Gosplan, gives a résumé of Kelvin's work on telecommunication, and points out how its development was strongly influenced by his ideas. Prof. Châtelain, the president of the Russian Section of the International Electrotechnical Commission, discusses Lord Kelvin's work in the domain of electrical engineering. Its exceptional value lies in the fact that Kelvin laid sure foundations on which later workers have built a noble superstructure.

MESSRS. W. HEFFER AND SONS, LTD., Cambridge, announce for publication in the autumn a translation, by T. R. Parsons, of "Practical Physical and Colloid Chemistry for Students of Biology and Medicine," by Prof. L. Michaelis, of Berlin, which work was written to meet the needs of biologists and physicians desirous of becoming acquainted with the more important applications of physical and colloid chemistry to the problems of life and disease.

In order to show French textile manufacturers that it is no longer necessary to purchase their machinery outside France, M. A. Renouard has an article of 69 pages in the May Bulletin of the Société d'Encouragement. It is well illustrated and shows that, since the War, French textile machinists have introduced improvements into spinning frames, looms, and other machines which place them in the front rank.

The Department of Mines of the Queensland Geological Survey is issuing a series of reprints dealing with Industrial Minerals, giving a brief summary of the occurrences, treatment, uses, values, and production of these minerals, with special reference to Queensland resources. Nine of these pamphlets have been issued dealing respectively with salt, asbestos, mica, molybdenite, platinum, nickel, graphite, manganese, and arsenic.

In the Annual Report of the Raffles Museum and Library, Singapore, for the year 1922, Major J. C. Moulton gives a list of 44 specialists whom he has induced to assist in naming the collections of the museum. Progress has been chiefly marked in the insect collections, and many papers describing new species contained in them have been published. "As a result the museum is becoming more widely known as a *live* institution, and an increasing number of inquiries have been received from many distant parts of the world concerning the fauna of Malaya." It is to be hoped that this good work will continue in spite of Major Moulton's transference to a higher post.

Report No. 27 of the Industrial Fatigue Research Board records the results of investigations into the following industries: the textile, metal, boot and shoe, pottery, glass, and laundry, and into some repetition processes. It is thus a compilation by means of which the findings of different investigators in different industries can be conveniently compared. The various recommendations have been grouped under the following headings: (*a*) working conditions, (*b*) working methods, (*c*) administrative. It is only by the slow accumulation of data from many fields that generalisation of scientific value can be made. We are yet far from generalisation, but these studies show the direction in which available evidence points and suggest further developments.

Our Astronomical Column.

The Opposition of Mars.—At midnight on August 22-23, Mars will be nearer the earth than it has been for more than a century. The conditions are, in fact, the best possible for a close approach. These conditions are attained when opposition occurs a week before Mars passes perihelion, from the fact that the earth is then nearer to its aphelion.

At these close oppositions, Mars considerably outshines Jupiter, and its ruddy light renders it a very striking object. It is 10° further north than in June 1922, so that the conditions for observation in England are not quite so hopeless as they were then.

Unfortunately, these very near oppositions have seldom been so fruitful in telescopic discoveries as those occurring somewhat later in the year. Thus Schiaparelli's work on the canals was mainly done in 1879 and 1881, though he was observing in 1877.

The late Prof. Lowell, whose long-continued scrutiny of the planet under all possible conditions adds weight to his opinion, explained this by August oppositions occurring at the dead season of canal development, when the supply of moisture from one polar region had exhausted itself, and that from the other had not commenced. It is interesting to learn that his widow is visiting Flagstaff; her presence will doubtless encourage the observatory staff to make the most of their splendid equipment. The 24-inch Alvan Clark refractor, and the seeing conditions at a height of 7000 feet in the Arizona desert, are universally admitted to be unrivalled. Prof. W. H. Pickering is remaining at Mandeville, Jamaica, until after the opposition.

Sun-spot Activity.—A noticeable feature on the sun's surface since August 1 has been a well-defined circular spot, in latitude 6° north, which passed through the centre of the disc between August 6 and 7. The history of this spot has been followed on the Greenwich photographs since July 9, when a large bi-polar group commenced to develop in a small area of faculæ seen at the east limb of the sun on July 6. The total area of the group reached 1/2000 of the sun's visible hemisphere about July 13, after which the rear components disappeared, leaving the leader to continue uninterruptedly in the following rotation. No pronounced magnetic disturbance occurred at Greenwich when the spot was near the sun's central meridian.

The period embracing a solar minimum is well known as one of transition; the passing cycle is represented by sporadic spots near the equator, whilst the spots of the coming cycle are appearing in higher latitudes (20°-35°). The last solar minimum is now definitely concluded, and although small equatorial spots might have been expected, a spot group of this extent and length of life is remarkable. It will afford additional data for determinations of magnetic polarities at Mt. Wilson, which are of added interest at this phase of the solar cycle in view of the observed reversal of polarities.

Two Notable Variable Stars.—The June Monthly Notices of the Royal Astronomical Society contain papers on the well-known variables Mira Ceti and β Lyræ.

The former is discussed by Dr. W. J. S. Lockyer, the star having been observed both for magnitude and spectrum at the Norman Lockyer Observatory, Sidmouth, last winter. The maximum was attained on January 29, in accord with Leon Campbell's prediction; the star was unusually faint, only rising to 4·9 mag., whereas it attained 2·2 mag. in 1906; it seems to have been the faintest maximum since 1886. The bright hydrogen lines were also feebler than usual; a discussion is given of their relative brightness. The more prominent dark lines were also studied, and indicated the presence of calcium, manganese, iron, aluminium, strontium, chromium, titanium. It was noted that there were several instances of the intervals between absorption lines having previously been mistaken for bright lines, and that apparently the only bright lines present are those of hydrogen.

Miss M. A. Blagg contributes a long paper on Baxendell's observations of β Lyræ, which ranged from 1840 to 1877. She concludes that the period is increasing, and gives the following formula for principal minimum: Julian Day $2398590{\cdot}57 + 12{\cdot}908\,E + {\cdot}0000037\,E^2$. She also finds a subsidiary variation with a period of 6·576 days; the fact of its being so nearly half the principal period increased the difficulty of analysis.

Research Items.

An Amerind Type from China.—Prof. Seligman ures in *Man* for August two examples of Chinese t of the T'ang period which provide a striking rroboration of the view put forward by Dr. dlička on several occasions, notably at the Nine- enth International Congress of Americanists (*vide* oceedings XIX. Int. Congress Americanists, p. 5), that a type identical with, or close to, the nerican Indian occurs over a wide area in Eastern ia. The first of these is a whistle, roughly spherical form, of a well-baked whitish paste, representing head, of which the face and scalp are covered with dull light green glaze. This might perhaps have en regarded as a freak, had it not been for a second d more striking specimen in the Eumorfopoulos llection. This is a small figurine of much the same ality as the whistle, and also covered with green ze. In both cases the features are distinctly nerind in cast, while the treatment of the hair ggests the lank locks of the characteristic American dian type.

Molluscan Problems.—The crystalline style of olluscs has always puzzled biologists, and even now ere is no clear indication of its full functions. obson performed a useful service in collecting gether all records of its occurrence not only in imellibranchs but also in Gastropods, and any mprehensive view of its function must apply to th these groups. Many writers have shown cently that the style contains an amylolytic ferment certain forms, but other equally good workers have t been able to find significant quantities of ferment the style of other species. There is therefore room r a comprehensive piece of work on this aspect the question, since generalisations from results of periments on a few animals are not yet valid. uxley suggested long ago that the style probably volved in the stomach, and Nelson has seen the volutions in a few bivalves, but more observations e again needed, as also of the use of the style to aw into the stomach the food-entangling mucus- rings as described by Orton and Worsnop in the ster. The ready solution of this organ in un- vourable conditions in some forms and its high sistance to solution in others indicates that the style ay have somewhat different functions even in closely lated animals. We shall therefore not be in a position dogmatise on the function of the style in molluscs til a great deal more information has been collected. nother old molluscan problem, which was regarded of great moment at one time, namely, the question the possibility of the intake of sea-water, has parently been settled. Pelseneer long ago acknow- dged the occurrence of a water system in the foot Naticidæ, but completely separated from the rculatory system and used for distending the foot burrowing, and similar cases have been recorded Lewis and by Mitra, who was also one of the first orkers to demonstrate the existence of a ferment the crystalline style. But no case of direct com- unication between the blood system and the terior has yet been demonstrated, and seems un- kely to occur. There still remains, however, the oblem of the possible absorption of water into the stem, either over the whole exposed surface or rtions of the surface of the body of a mollusc.

The Twinning and Monembryonic Develop- ent of Platygaster.—Messrs. R. W. Leiby and C. Hill contribute an interesting account (*Journ. gr. Res.*, Washington, vol. 25, No. 8, 1923) of the development of *Platygaster hiemalis*, a hymenopterous parasite of the Hessian fly. The female deposits a group of four to eight eggs in the egg or in the young larva of the host. During maturation two polar bodies are formed in the egg, and these unite to form a single polar nucleus in the anterior region of the egg. Maturation is stated to be identical in fertilised and in unfertilised eggs. After maturation the male and female pronuclei fuse to form the cleavage nucleus, which lies in the posterior part of the egg. In the unfertilised egg the female pronucleus is found in a corresponding position. The portion of the egg containing the cleavage nucleus becomes differentiated and forms the embryonic region; the remainder of the egg containing the polar nucleus is homologous with the trophamnion and paranucleus of previously described polyembryonic insects—its function is to nourish the embryos until they are young larvæ, and can feed for themselves upon the host. The embryonic nucleus and the polar nucleus each undergo division into two and then four. The embryonic region in some of the eggs then divides to form two embryonic regions which become separated from each other—each carrying with it two of the four paranuclear masses. This separation results in the production of twin germs, each of which develops into a larva. The embryonic region of other eggs does not separate into two, and such eggs produce a single larva. The twinning development, here described for the first time, illustrates a simple type of polyembryony.

Rainfall in Australia.—The rain map of Australia for 1923 compiled by the Commonwealth Meteorologist shows the distribution of rain for the year and for each separate month. There are also a number of charts showing the areas with rainfall above the average in recent years. The chief maps are based on the records of some 1300 well-distributed stations. About 22 per cent. of the continent had a rainfall above the normal, but the excess was mainly in the west, south-east, and Tasmania, while in 1922, when the area of excess reached about the same percentage, it was mainly in the north. In Queensland and parts of northern New South Wales, the dry conditions which had prevailed in 1922 continued and intensified into conditions of severe drought. It was only in June and December that the rainfall was at all satisfactory. In south-eastern Australia the fall was poor during the first half of the year. Conditions during the cereal-growing period were very favourable throughout most of the wheat region, but in northern New South Wales and Queensland crops failed on account of the drought.

Opalescence at and near the Critical Point.—M. A. Audaut, in the May-June number of the *Annales de Physique*, describes a very comprehensive investigation of this phenomenon for five liquids with high critical temperatures. He measured both the diminution of the intensity of the transmitted light, and the intensity of the light scattered at right angles to the line of incidence, and found that the critical opalescence has the same intensity for a given substance when the experimental conditions are the same, and is not due to dust or impurities. Slow change of temperature and thorough stirring are necessary to obtain well-defined opalescence, a rate of one degree change per hour having been adopted. The opalescence was found to be a function of the temperature, of the wave-length of the light employed, of the amount of substance in the tube, the "filling," and

of the nature of the substance. The appearances observed at different temperatures and with different fillings agree with the theory of Einstein and Smoluchowski, which explains the opalescence as due to molecular agitation, using the analogy of Brownian movements. There is a critical filling, with maximum opalescence, which in this case is found at the same temperature with rising and with falling temperature; this temperature coincides with the critical temperature, which can be determined with accuracy by measurements with different fillings. The method gives for ether and ethyl acetate 193·3° and 249·8° for the critical temperatures, and 0·259 and 0·306 for the critical densities. The number, N, of the molecular aggregates concerned per c.c. can be deduced by means of the theory from the observations of the opalescence; for ether, at 2·5° above its critical temperature, two values were obtained for N: 62×10^{22} and 58×10^{22}.

ADSORPTION AND CATAPHORESIS.—In the *Comptes rendus* of the Paris Acad. Sci., June 23, M. K. v. d. Grinten describes observations made with the ultramicroscope on a suspension of fine particles of the same glass as that employed in the construction of the trough containing it. Platinum electrodes 40 cm. apart were placed in the trough, and the potential difference between them was 10 volts. The velocity of the particles near the glass walls was in the opposite direction to that of those midway between them; the velocity of the latter, near the positive pole, was double that along the wall near the negative pole. When the thickness of the trough is more than 0·5 mm. the velocity of the particles in the middle region no longer varies with the thickness. This indicates that the liquid in the middle region remains at rest and the measured velocity is the true velocity of the particles with respect to the liquid. If electrolytes are added the cations of which are adsorbed, the velocity of the particles diminishes, and reverses for a certain concentration of the electrolyte. Methyl violet (*violet crystallisé*) was used as the added electrolyte, and the maximum number of molecules adsorbed per sq. cm. of glass sheet was found to be $1{\cdot}6 \times 10^{14}$. At small concentrations the adsorption grows rapidly with the concentration, but from the concentration $n/10000$ on it grows less rapidly towards the maximum, when it is concluded that a monomolecular layer is formed over the whole surface of the glass. The curve showing the relation of the cataphoresis velocity to the concentration, and that showing the relation of the number of adsorbed molecules per sq. cm. to the concentration, have the same form; starting from concentration $n/10000$, the two curves rise almost perpendicularly to the X axis. Similar results were obtained with suspensions of selenium. It appears then that each particle in the suspension is covered with a monomolecular layer when a certain concentration is reached.

WHAT IS MATTER?—In the issues of *Die Naturwissenschaften* for July 11, 18, and 25, Prof. H. Wehl, of Zurich, passes in review the various answers which have been given to this question. Of these the older "substance theory" has played its part and disappeared, leaving the "field theories" of Mie and others and the "dynamical theories" in possession of the stage. Some form of dynamical theory gives, according to Wehl, the greatest insight into the question, and he outlines his own view as follows: Matter is an agency which generates a field, the field a medium which propagates the action of one body on another. An "active mass" m generates about itself a field $m/4\pi r^2$ and a "passive mass" m' placed in this field is acted on by force $mm'/4\pi r^2$. By a proper choice of units the passive and active masses of body may be made identical, and the conception the field as a flux from the active mass gives t inertia of the mass as due to the field it generat about itself.

DEVELOPMENT OF PHOTOGRAPHIC LENSES.—Tho who are interested in the history of the developme of lenses for photography will find in the Augu number of the Royal Photographic Society's Journ an exceptionally valuable contribution by Pr Moritz von Rohr. Since the publication of h "Theory and History of the Photographic Objective in 1899, he has found many new facts, and it is the that he here records. He refers to work by Scheiner in 1618, J. G. Leutmann in 1719, Thom Young in 1800, Coddington, Airy, and others, in t prephotographic period. Then follow accounts A. S. Wolcott's pioneer work in 1843 (who appears have been the first to produce a symmetrical doubl and a revolving diaphragm), a symmetrical doubl with plane cemented surfaces by H. Fitz, and t efforts of American opticians (1860–66) in the pr duction of wide angle lenses. The great theoretic importance as well as the practical efficiency of t negative lens used by Piazzi Smyth to flatten t field of the portrait lens in his small camera that to plates one inch square is discussed. The author h obtained from Mr. J. Stuart two letters written Monckhoven (1865–67) recommending Thomas Ro to take up the manufacture of H. A. Steinheil's aplanats. A full translation of these letters is give and the originals were presented to the Royal Phot graphic Society. The paper concludes with a lo list of references to the sources of information.

CHEMISTRY OF INSULIN.—*Chemistry and Indust* of July 18 contains an account of a paper by Mr. F. Carr, of British Drug Houses, on the manufacture insulin. An account of what is known of the chemistr of insulin, the most important property of which is i action in causing the disappearance of glucose fro diabetic blood, at the rate of 3 grams of sugar p 0·0001 gram of insulin in two hours, is first give Insulin appears to be sparingly soluble in water at i isoelectric point of $P_H = 5{\cdot}2$, but readily soluble a other points near neutrality, precipitated by ha saturation with ammonium sulphate and sodiu chloride and other reagents, insoluble in absolut alcohol, free from phosphorus, tryptophane, an tyrosine when pure, but containing organic sulphu Insulin from ox-pancreas gives the biuret reactio but that from skate-pancreas does not. It does n pass a collodion ultrafilter and is destroyed by pepsi and trypsin, and therefore appears to be of protei like structure. Insulin is extracted from anima pancreas, which is the part of the body in which it mainly stored, and recent experiments show that i is present in a more easily separable form in man fishes near the gall bladder. The method of manu facture is rather complicated, but depends essentiall on extracting the disintegrated pancreas, rendere acid to P_H 2·5 or alkaline to P_H 7·0, with 65-70 pe cent. alcohol, in which little enzyme is dissolve cooling to −5°, filtering or centrifuging, concentratin at low temperature to one-tenth the volume, extract ing the fat, precipitating the proteins with absolut alcohol or ammonium sulphate at P_H 5 and furthe separation of the separated proteins with alcohol an picric acid. The large scale operation is continuous and a flow sheet is given. As a result of improvements the selling price of insulin has been reduced fro 25*s.* to 2*s.* 8*d.* for ten doses. The really wonderfu results of insulin treatment in advanced cases o diabetes are set out.

The Fourth International Congress of Refrigeration.

THE fourth International Congress of Refrigeration was held in London in June last. The Congress was organised by a committee of the British Cold Storage and Ice Association, working in conjunction with the Institut International du Froid. This International Institute is an organisation in which each State, Dominion, or Colony, signatory to the International Convention, is represented by delegates appointed by the participant State in a number proportioned in accordance with the amount of annual subsidy, varying from 1000 to 12,000 francs. It is interesting to note that forty-eight countries have signed the International Convention.

The Institute devotes its energies to further the science of refrigeration; to encourage the study of the best solutions of questions relating to the conservation, the transit, and the distribution of perishable produce; to the publication of all information relating to the world's frozen-food situation.

The study of the above-mentioned subjects is pursued by sixteen separate commissions. The function of the International Congresses is to co-ordinate and afford a common meeting ground for the members of these commissions and to all interested in refrigeration.

The work of the London Congress was subdivided between seven sections dealing respectively with: 1. Scientific Questions—Physics, Units, and Biology. 2. Refrigerating Materials—Machines, Insulating Materials and Testing. 3. General Applications of Refrigeration—Food, Agriculture, Ice, etc. 4. Refrigerated Transport—Railway and Steamship. 5. Legislation. 6. Education and Propaganda. 7. General Economics and Statistics. Thus one section would embrace the subjects coming within the purview of a number of separate commissions.

The meetings of the Congress were well attended by those engaged in the practical side of refrigeration. The title "Congress of Refrigeration" failed to attract many physicists, although Section 1 had on its programme a fine series of papers from the Leyden Cryogenic Laboratory.

The character of the papers will be realised from the following titles selected at random: "Organisation of the Work of Commission No. 1" (Kamerlingh Onnes). "Report on the Freezing Point Temperatures of Organic Substances suitable for Use as Reference Points for the Low Temperature Scale" (Jean Timmermans). "The Isotherms of Hydrogen, from −217° C. to −240° C." (J. C. Swallow). "Report on the X-ray Investigation of the Constitution of the Liquid and Solid States of Substances at Low Temperatures" (W. H. Keesom). "Low Temperature Investigations in the Service of Cosmical Physics" (L. Vegard).

The papers of a biological character submitted to Section 1 were rather disappointing, and it was evident that the majority of the contributors did not regard the Congress as the place to discuss purely scientific matters. It is a pity that this outlook should prevail, for it is obvious that an international congress which gathers under one roof the diverse interests concerned can exert an enormous influence on the progress of refrigeration on both the theoretical and the practical sides. Hence, on the purely biological side of the science of refrigeration there is but little which calls for comment, so far as the present Congress is concerned.

Some of the most interesting of the papers on the practical side were those dealing with the transport of refrigerated produce by land and sea and those on special applications of refrigeration. Of the papers dealing with the marine side, one might be mentioned —"Special Methods of Construction of Ships and Refrigerating Appliances for Vessels employed on Long Voyages" (A. R. T. Woods).

As regards land transport, the paper on "The Influence of Refrigeration in the Preservation of Fruit with Special Reference to South African Export Varieties" (I. B. Pole-Evans and Edgar A. Griffiths) is noteworthy, as it records the results of experiments on special trucks carrying fruit a distance of 1000 miles through semi-tropical heat.

The paper on "Temperature and Metabolic Balance in Living Plant Tissues" (F. Kidd and C. West) is a useful sketch of some recent work in America and Germany.

The work of the Insulation Sub-Committee of the Food Investigation Board was summarised in a paper of about eighty pages with the title "The Scientific Study of Heating Insulating Materials" (Sir Richard Glazebrook and E. Griffiths).

An interesting contribution on one of the special applications of refrigeration was that on "The Application of Refrigeration to the Ventilation of Mines" (F. A. Willcox and J. D. Farmer).

Mr. W. B. Hardy, director of the Food Investigation Board, gave an admirable sketch of what he considered to be the correct function of the Food Investigation Board and the work of a research station. He pointed out that of the problems which an industry presents, some are fundamental and far-reaching, others special and local. He quoted two examples to illustrate what the Board conceived to be their special province of work. One was the problem of the freezing of beef and most white fish. Can these materials be so frozen as to recover their original state on thawing? When beef is thawed after being frozen, its texture is impaired, and it drips a fluid rich in dissolved nutritive material. This is due to that separation of water from other constituents which is a common feature in the freezing of solutions. Is it possible so to modify the whole cycle of physical events compressed in freezing and thawing as to bring this separation of water under such control as will lie within the four corners of a possible commercial process? No answer is yet forthcoming, because the theory of the freezing of tissues is yet in its infancy. Animal tissues are colloidal structures, and of the effects of low temperatures on colloids little is known. This is a fundamental problem because its solution involves the whole theory of the freezing of tissues. If and when it is solved, and it may be years before that difficult end is attained, any feat of freezing should be possible, or, to be more exact, the possibilities and impossibilities of freezing as a mode of preserving animal or plant tissues should be capable of fairly exact delimitation.

The other problem put forward by Mr. Hardy was purely physical. The Board were consulted as to the following:

A certain store was cooled by a fan driving air over calcium chloride brine, the cold air being then supposed to circulate throughout the chamber. Meat stored there became discoloured and unpleasant to sight and touch. This was ascribed to putrefactive organisms—to bacteria, in short. The solution of the problem proved simple. Bacteria as the *causa vera* were readily ruled out. The wind from the fan produced an invisibly fine spray of brine which settled on the surface of the carcases, where the calcium chloride reacted with the red colouring matter hæmoglobin to produce methæmoglobin. The scientific interest up to this point is small, and the problem,

though of some practical interest, does not rise above the level of the ordinary works laboratory. A study of the air currents in the chamber, however, revealed the fact that the fan, though seemingly placed where it would circulate the whole body of enclosed air, did as a matter of fact merely puddle in its own neighbourhood, producing powerful vortices on the surface of the brine. This and many similar instances have convinced the Board that the principles which underlie the movement of air in a space partly occupied by solid masses, such as the cargo in a hold, or the carcases in a store, are not clear, and therefore they have arranged that this general fundamental inquiry shall be prosecuted at the National Physical Laboratory.

This example will serve to show how the particular leads to the general; but general solutions are not reached readily, and, therefore, if each particular problem is regarded only as the door to the general, the number of problems which can be undertaken by the small staff at the disposal of the Board is limited.

The papers on the practical engineering aspect f cold storage were so numerous, and the impressi which the Congress left upon one was that t progress made on the purely technical side has been considerable, that it threw into strong relief t inadequacy of our knowledge on the fundamen problems of biology.

A Congress such as the one under review, with strong international backing, should have been t occasion for a frank review of the situation and discussions on the fundamental problems with whi the industry is faced. The proceedings of the successive congresses could be made to serve definite landmarks in the history of the science refrigeration by epitomising the advances made the intervening years both in pure and appli science, in so far as they relate to the preservation perishable food-stuffs, and by formulating the gene plans of attack on the new problems.

EZER GRIFFITHS.

Mechanism of Cell Growth.

IN the higher plants, new cells are formed and new tissues arise by the activity of certain definitely localised and clearly characterised tissues, the meristems. In the Dicotyledon, these are found at the apex of root and shoot, that is, at either end of the growing axis; in addition, two continuous cylinders of meristem, the cork phellogen and vascular cambium, run lengthwise through the axis and contribute to its subsequent increase in girth. Within these meristems proceeds the construction of new protoplasm, with subsequent mitotic division into new cells as nuclear and cytoplasmic substance accumulates. In such a plant, then, the fundamental metabolic synthesis inseparable from growth, with the subsequent multiplication of the cells of the embryonic tissue, can be visualised as proceeding in strictly localised regions, and the question as to the conditions which promote such growth and division can to some extent be investigated experimentally. Within recent years the meristems have been examined from this point of view. It is clear that if their investigation gives any information as to the condition favouring such a fundamental process as the growth and multiplication of embryonic cells, this information may have very general importance and illuminate a wide range of problems.

From this point of view, an article by Friedl Weber in *Die Naturwissenschaften* for April 18 is of exceptional interest, as it reviews the recent plant physiological approach to these problems from a wide angle and with a wealth of documentation (for citation to original papers referred to below, reference must be made to Weber's paper).

The best known contribution to the conditions governing meristem activity is Haberlandt's theory as to the circumstances which give rise to a new meristem when the plant is wounded and a cork phellogen arises as a result. In this case, cells that have differentiated, and ceased to grow, return again to the embryonic state, and Haberlandt traces this to the effect upon these cells of growth-promoting hormones released from the injured cells. Weber examines the view sympathetically, and has himself used it to explain the forcing of buds from their winter's rest by freezing, narcotics, and various other methods by the assumption that the efficacity of the treatment depends upon the release of such hormones as the result of "physiological wounds" within the bud. Schillings' experiments, however, in which stems of flax and hemp, bent so that they droop earthwards, grow vigorously in the region the flexure, tell strongly against Haberlandt's vie as this stimulus to growth disappears, although t injury does not, when the shoot is supported in t erect position after bending. But the greatest d advantage of Haberlandt's view is that it throws light upon the normal meristematic activity of t uninjured plant.

From this point of view, therefore, Weber finds wider significance in the views recently develop by Priestley and Woffenden. These investigato similarly start from an examination of wound co but the conclusions they reach that its formati depends upon, first, a blocking of the wounded surfa and then an accumulation of sap in the walls a intercellular spaces below this block, enable the by consistent use of the same developmental facto to give a causal explanation of the position of t normal cork phellogen clothing root and ste Weber then proceeds to a discussion of the mo general suggestion as to the conditions for activi of the intercalary meristems of the Dicotyledo recently advanced by Pearsall and Priestley. The authors have pointed out that these two cylinde of meristem appear to be functioning across tv reverse gradients of hydrogen ion concentration, t vascular cambium lying between acid xylem within a relatively alkaline phloem without, whilst the co phellogen has within it the cortex at about P_H but outside it cells, the walls of which are bath in fatty acids with a reaction of $P_H 3$. Web examines in the light of a wealth of relevant da the suggestion of Pearsall and Priestley that prot plasmic synthesis, and therefore meristem activit takes place, across this gradient, at the iso-electr point of the cell proteins, the protoplasm at th reaction losing water to cells on either side whic being at other points on the hydrogen ion gradien swell and vacuolate, withdrawing water from th meristem.

Weber points out that many other physico-chemic properties of the colloidal state of protoplasm a involved in addition to the power of absorbing wate and emphasises that the delicate equilibrium of thes properties, which alone permits of protoplasmi synthesis and mitotic division, probably will onl be maintained over a limited range of hydrogen-io concentration. From this point of view, he re examines Kühns' classical experiments upon nuclea and cell division in Amœba, and directs special atter tion to the experiments which, by micro-dissection c

by other methods, throw light upon protoplasmic viscosity, and show that alterations of viscosity are quite generally characteristic of mitosis and the activities of embryonal cells.

From the same point of view, Weber points out that high temperatures, narcotics, and other factors influencing mitosis are factors capable of influencing protoplasmic viscosity, as shown by Heilbrunn in his experiments upon sea-urchin eggs. Similarly, Koernicke has shown that under X-rays, and Hartmann that at high temperatures, all the cells of the meristem of the root apex vacuolate. Weber also points out that the rounded nucleus characteristic of the embryonic cell suggests a different and more plastic physical state of nuclear protoplasm, so that the shape is more controlled by surface tension than in the case of the variously shaped nucleus of the differentiated cell that has ceased to divide.

Weber marshals much evidence to show that the hydrogen-ion concentration of the medium can affect the physico-chemical state of the protoplasm, and directs attention to Spek's interesting suggestion that at mitosis, a base, the bye-product of nuclein synthesis, escapes into the cytoplasm with consequent swelling of the plasma colloids and as a result a stimulus to increased nuclein synthesis, so that the process is autocatalytic. Spek explains the cessation of cell division as brought about by a change in permeability permitting increased entry of salts, which neutralise the action of the base released from the nucleus. Certainly in the mitosis of sea-urchin eggs the influence of the hydrogen-ion concentration of the medium has been established as in the experiments of Vles and his co-workers. Lyon has shown that the carbon dioxide production during mitosis varies at the different stages recognised by the cytologist, whilst Jacobs has tried to correlate these striking fluctuations in carbon dioxide output with the equally striking viscosity changes. As Weber points out, such fluctuation of carbon dioxide output will influence the difference between the reaction of the egg plasma and the outside medium.

The rhythm of cell division may find some explanation in the respiratory production of carbon dioxide. Thus Lapicque has shown that the reaction of the medium in which Spirogyra is growing is affected by carbon dioxide production in the dark and its disappearance during photosynthesis in light, and Weber suggests that here may lie the explanation of the fact that cell division in this plant occurs only at night.

Starling is cited for the view that the problem of cancer is the problem of the control of cell growth. Recent studies of cancer with physico-chemical methods enable Weber to refer to investigations indicating that the cancer cell owes its peculiar growth qualities to the medium, the tumour plasma, in which it lies, and that one important factor of this medium is hydrogen-ion concentration.

Weber thus brings a very wide range of phenomena of great general interest under review, and points out in conclusion that the suggestion of Pearsall and Priestley, that the hydrogen-ion concentration is a material factor in meristematic growth, admits of experimental investigation, Heilbrunn, Meier, Endler, and Robbins, amongst others, having suggested methods for determining the iso-electric point of the protoplasm.

Cambridge and the Royal Commission.

PROVISIONAL SCHEME.

THE University Commissioners have communicated to the University of Cambridge a provisional scheme for the inauguration and organisation of teaching in the University on the general lines of the recommendations of the Royal Commission. They propose to draft necessary statutes and ordinances themselves to carry out their scheme, but publish their proposals in outline in order to give members of the University an opportunity of expressing their opinion about the proposals.

It is proposed to constitute as from October 1, 1926, eleven faculties in the arts group and seven in the science group. In the science group there are to be agriculture, biology, engineering studies (including aeronautics), geographical and ethnological studies, mathematics (including astronomy and geodesy), medicine, physics, and chemistry. The faculty of biological studies is to be divided into two sections, each with separate departments: A. (1) botany, (2) genetics, (3) geology, and (4) zoology. B. (1) biochemistry, (2) experimental psychology, (3) human anatomy, (4) parasitology, (5) pathology, (6) physiology. The faculty of physics and chemistry is to include the following departments: (1) astrophysics, (2) chemistry, (3) mineralogy, (4) physics.

The separate faculties will be composed of official university and college teachers in the appropriate subjects (including fellows of Girton and Newnham Colleges) and others appointed by the Board of the Faculty. The Board of a Faculty will consist of the professors in the subjects concerned, a certain number of nominees of the faculty, of the Board and of the Council of the Senate, together with representatives of cognate studies. The average number of members of a Board, according to the detailed scheme suggested by the Commissioners, is sixteen.

The new General Board of Studies is to consist of four members elected by the group of arts faculties, four members elected by the group of science faculties, four members of the Council of the Senate, and two persons nominated by the Council, with the vice-chancellor as chairman. The number of university lectureships (and demonstratorships) would be determined by the University for each faculty on the recommendation of the Board of the Faculty and of the General Board. The appointments would be made by a standing committee for each faculty of the vice-chancellor, the head of the department, three members of the Board of the Faculty appointed by the Board, and two persons appointed by the General Board. The normal tenure would be for three years in the first instance, and, on renewal, so long as the lecturer was doing his work satisfactorily, until the retiring age of sixty-five.

According to the scheme, all fees for lectures announced by the General Board would be paid to the University into faculty or departmental funds, the lecturers to be paid a basic wage by the faculty for an obligatory minimum of teaching work, with a scale of increments on the basic salary, with continued tenure of a post, and with additional payments for extra work done. It is contemplated that the University will be able to inform the faculties, before they finally create their new lectureships, how much money, if any, the University can put at the disposal of each faculty board in addition to the fees credited to it.

A great amount of work must lie before the Commissioners and various bodies of the University in getting the scheme into working order; a great amount of work must have been done on it already. It represents the completion of a process which has

been going on for a considerable time by which the organisation of the teaching and the actual teaching itself has been slowly but steadily passing out of the hands of college lecturers into those of university staffs. The creation of the large scientific laboratories and departments has accelerated the change, which is already half completed. The University takes more conscious control of developments and changes in studies. It remains to be seen whether improved organisation will mean better efficiency or whether the initiative of individual colleges fostered in the past may be crushed by the burden of machinery. As ever in such cases, it all depends on the quality of the men who become responsible for driving the machine.

Among other proposals which the Commissioners contemplate is permission for a professor to be continued in office after reaching the age of sixty-five up to, but not beyond, the age of seventy. They also contemplate throwing open all professorships, readerships, lectureships, and examinerships to women. This proposal to put women teachers on the same footing as men in the matter of the organisation of teaching removes one of the serious grievances remaining for women at the University. Even though they may not vote in the final decisions of the Senate on matters of educational policy, they will be free as members of a faculty to take part in the more important preliminary discussions which ultimately determine the changes of policy. The Commissioners do not propose to force upon the University, against its expressed wish, the admission of women to membership and to a share in the government of the University. That is to be left to the University itself to settle.

University and Educational Intelligence.

BRISTOL.—A prospectus of the Faculty of Engineering, which is provided and maintained by the Society of Merchant Venturers in the Merchant Venturers' Technical College, Bristol, has just reached us. Courses of study are available at the College for persons intending to engage in civil, mechanical, electrical, or automobile engineering, and particulars of these courses are given in the prospectus. The ordinances and regulations relating to degrees and diplomas in engineering subjects are included, and some particulars of the Bristol sandwich-system of training engineers are also given. The prospectus can be obtained from the registrar of the Merchant Venturers' Technical College, Bristol.

CAMBRIDGE.—Mr. W. S. Thatcher has been appointed Censor of the Non-Collegiate Students.

LEEDS.—With the view of encouraging the revival of the University Extension movement, the West Riding Education Committee has decided to make towards the cost of an approved course of extension lectures such a grant as will cover the actual deficit incurred, or 75 per cent. of the total expenditure, on condition that at least 30 persons undertake to enter for the whole course, and that the lectures are open to the public at a charge not exceeding 3*d*. per single lecture. The fees for lectures range from 22*l*. 10*s*. for a course of 6 to 76*l*. 10*s*. for 24, and the only other charges besides incidental local expenses, such as hire of hall and advertising, which are borne by the local committee, are the lecturer's travelling expenses and a fee of not less than two guineas (varying according to the number of candidates) for the examination, if one is held. The panel of lecturers includes 33 members of the University staff, of whom 8 are professors. The range of subjects is very wide: the following are specimen headings—Greek ethics, archæology and architecture, phonetics, the Irish literary movement, social psychology, riches and poverty, Spanish art, How the Empire is governed, French history since 1815, the gases of the atmosphere, fresh-water biology, types of respiratory structure, the antiquity of man, radio-activity, application of colloid chemistry to industry, British birds, enzymes, bacteriology from the medical, public health, and chemical points of view, personal hygiene.

AN advisory chemist in the faculty of agriculture, University College, Reading, is shortly to be appointed. Particulars are obtainable from the Registrar of the College.

THE trustees of the Busk studentship in aeronautics, founded in memory of Edward Teshmaker Busk, who lost his life in 1914 while flying an experimental aeroplane, have appointed Mr. John Cowan Stevenson, of the University of Glasgow, to the vacant studentship.

A DEMONSTRATOR is required in the mathematics and mechanics department of the Royal College of Science, South Kensington. Candidates must possess engineering experience, and send their applications to the secretary of the college not later than September 5.

APPLICATIONS are invited by the Director of the School of Medicine, Cairo, for the professorships in the school, of Physics, Clinical Medicine, and Clinical Surgery; also for the post of lecturer in physics in the institution. In the latter case candidates must be of Egyptian nationality. Applications must reach the director by September 15 at latest.

APPLICATIONS are invited for the appointment of lecturer in physics and the directorship of the Viriamu Jones Physical Research Laboratory of the University College of South Wales and Monmouthshire. Applications (six in number) and testimonials must be received not later than September 10 by the Registrar of the College, Cathays Park, Cardiff.

THE University of Calcutta "Poverty problem study" organisation which has been at work for some years has succeeded in promoting the formation of a limited liability company for the establishment in the Pareshnath Hills of co-operative educational colonies, such as Capt. Petavel, Principal of the Kassimbazar Institute, has been advocating in his university lectures on the "Poverty problem." The Company proposes to set up an agricultural college "where professors and students will be provided with sufficient land for self-support and education." Each student on completion of his course, and having obtained a university diploma, would be helped to acquire, as a member of a colony, a plot of ground with bungalow, well, bullocks, plough, etc. The scheme is described in the first number of a new periodical, "Bread and Freedom," edited by Capt. Petavel.

INTERCHANGE of teachers between universities within the Empire is one of the subjects that were discussed at the recent Imperial Education Conference in London organised by the League of the Empire. One speaker described as an object lesson to the universities of the Empire the Chicago University summer school, which attracts professors and lecturers from all parts of the United States as well as from abroad. We have lately received a University of Colorado Bulletin which gives an account of this University's summer quarter, extending from the middle of June to the end of August. This year the staff includes no less than fifty instructors from other

stitutions, among whom are professors and other embers of the staffs of universities in twenty other tates. Many are, no doubt, attracted by the niversity's advantages of climate and picturesque rroundings. A permanent camp is maintained uring the summer quarter at Arapahoe Falls in the ocky Mountains, about 25 miles distant, for the enefit of university students and teachers.

Adult education in Ireland was the subject of an ddress by Mr. George Fletcher, of the Department f Agriculture and Technical Instruction for Ireland, t the annual congress of the Irish Technical Instruction Association on June 4. For many years there ave been complaints that the effectiveness of echnical instruction in Ireland is much less than it ight be, because the standard of general knowledge f the students is low. It is mainly on the ground hat it would remedy this defect that Mr. Fletcher rges the inauguration of schemes for the extension f University teaching in towns and for the establishment of community centres with village halls in ural districts. Hitherto there has been no movement in this direction in Ireland comparable with the University Extension movement in England. The Royal Dublin Society, a few years ago, allocated 200*l.* or the initiation of courses of lectures; a panel of ecturers was framed and syllabuses were prepared, ut the work had barely begun when travelling became almost impossible, and the scheme was bandoned as impracticable. Its resuscitation has ow been recommended. It is thought that the ransfer of Technical Instruction from the Department of Agriculture and Technical Instruction to the Department of Education, which took place on June 2, 924, may tend to the establishment of conditions avourable for voluntary enterprises in the field of dult education.

"Non-university resources for graduate study and esearch" formed the subject of two interesting papers ead before the Association of American Universities ast November and published recently. President Wilbur, of Stanford University, argued in favour of all ew research projects being brought directly into the domain of some university or group of universities, nd also against the constitution of "research rofessorships" and special research institutes isolated rom "the great normal university current." In ertain fields the Pasteur Institute, the Rockefeller nstitute in New York City, and other organisations or research independent of universities have not nly achieved conspicuous success but have also "set he pace" for university research work. This kind f development of research is, however, less advantageous to the community than development within the universities, for the following reasons: ts overhead expenses are greater, it does not provide uch good opportunities for the training of young esearch students, or for the benefits of membership f a faculty and association with members of other aculties, and it tends to involve a more urgent ressure to produce visible results. President Wilbur irected attention to the recent decision of the anners' Council to place its research project at the University of Cincinnati, the Council having come to the conclusion that "the university atmosphere is the right place for research." This view may be compared with Sir Frank Heath's pronouncement at the May conference of British universities to the effect that modern demands seem to point to the necessity for at least four types of organisation for research: universities, central research institutes, industrial research laboratories run by the industries themselves, and laboratories of individual firms.

Early Science at the Royal Society.

August 17, 1664. The engine to measure refractions was produced, examined and approved of, and Mr. Hooke the inventor of it, appointed to begin at the next meeting to try experiments in it; as also to give a description of this engine to be kept in the Register-book.—Dr. Goddard was desired to describe his instrument with strings and pulleys intended for a hygroscope, and to take notice of the uselessness thereof, as it had been hitherto contrived, and to think upon another way.

1687. Sir John Hoskyns communicated the following receit of one Simeon Pauli for a varnish to coat and preserve dried plants; infuse in spirit of wine the seeds of wormwood; and then dissolve therein as much gum elemi as it will take; and with this varnish cover the plant. This was thought to be a good means to preserve insects from perishing.

August 18, 1670. Mr. Hooke reported to the society, that he had already found so much, as to suspect some parallax of the earth's orb, and conceived, that it would be more sensible half a year after. He said, that by a perpendicular tube he observed the stars, which pass our zenith, at different times of the year, and by noting, whether the same star be at those different times of observation at the same distance from the zenith or not; concerning which he affirmed, that a certain star was then less distant from the zenith than it had been a month before.

August 19, 1680. The subject of filtration and rising of liquors in small pipes was debated. The difficulty of them appeared; viz., first, from the imperfect exhaustion; and secondly, from the uncertainty of the rising of the same liquor in the same pipes at several times.—Dr. King related that he had observed six or seven sorts of animals, a thousand of any of which were less than a globule of blood.

1663. Mr. Hooke gave in a picture of the stones taken out of the heart of the earl of Balcarres. The lord viscount Brouncker promised to get the same done in plaister.

August 20, 1662. Dr. Wallis's written discourse about Dr. Goddard's experiment of weighing glass canes with the cylinders of quicksilver standing in them according to the Torricellian experimt. was delivered in; but because the understanding thereof depended greatly upon the schemes annexed to it, the reading of it was deferred till the next meeting: and the amanuensis was ordered to draw the said schemes in great upon a large paper that every member might look upon them with conveniency.—Mr. Powle to be written to by Mr. Oldenburg, that he would send the society an exact description of the whispering place in the cathedral of Gloucester.

1684. Mr. Henshaw having propounded to try, whether a thermoscope, exhausted of air, with the liquor in it, exhausted of air too, might be sensible of cold and heat, as ordinary thermoscopes are; the thing was tried, and found that the effect was not sensibly altered by the absence of the air.

August 21, 1661. Mr. Colwall read his "Relation concerning the making of Alum," for which he received the thanks of the society, and it was ordered to be registered.

August 22, 1678. Mr. Hooke delivered to the Society an antient urn of glass, taken up in Spittlefields upon digging cellars there, presented by Sir Christopher Wren. There was this remarkable in it, that it seemed to be made after quite another manner than that used by the present workman in that art, it having no place at the bottom thereof; nor any visible sign how it could be held, whilst the lip and handle thereof were joined to the body.

Societies and Academies.

PARIS.

Academy of Sciences, July 16.—M. Guillaume Bigourdan in the chair.—V. **Grignard** and R. **Jenkins**: Mixed organo-aluminium compounds. The iodides of monoethyl- and of di-ethylaluminium. Dry ethyl iodide reacts with aluminium powder in the absence of oxygen, giving a mixture of the compounds $((C_2H_5)_2 . Al I)_2$ and $(C_2H_5 \cdot Al I_2)_2$. Both compounds are spontaneously inflammable in air, and in contact with water give pure ethane.—Jacques **Chapelon**: The representations of an integral number by certain forms with six variables.—Enrico **Bompiani**: The second fundamental form of a surface.—G. **Maneff**: Gravitation and the principle of equality of action and reaction.— — **Lémeray**: General conditions which must be satisfied by a theory of the universe in agreement with general relativity.—E. **Tournier**: A new method of calculating the power of the reciprocating steam engine.—Louis **Roy**: Electromagnetic waves in continuous media in motion.—Maurice **Curie**: The photo-electric effect and temperature.—P. **Lebeau** and Ch. **Bedel**: The estimation of carbon monoxide. The reagent recently proposed by Damiens (cuprous oxide dissolved in concentrated sulphuric acid) for the absorption of carbon monoxide is modified by the addition of β-naphthol. This addition renders the Damiens reagent more stable, and less liable to absorb oxygen.—E. **Kayser** and H. **Delaval**: Radioactivity and nitrogen-fixing organisms.

CAPE TOWN.

Royal Society of South Africa, June 18.—Dr. A. Ogg, president, in the chair.—R. S. **Adamson**: Preliminary note on secondary growth in some Iridaceæ. Three closely allied genera, Nivenia, Witsenia and Klattia, possess woody stems with continued secondary growth. The secondary growth has the same general features as that described for the arborescent Liliaceæ, but these plants differ in two features:—(1) The secondary bundles, or the inner ones, are very close together, often in contact. The radial arrangement of cells is obscured to a large extent. The bundles arise from a number of cambium cells. (2) In old stems the secondary tissues are arranged in zones (annual rings), a feature not previously described for monocotyledons.—Sir Thomas **Muir**: Note on systems of determinants with sets of deleted elements.—J. **Moir**: Colour and chemical constitution, Part XIX., Organic fluorescence.—S. H. **Haughton**: On a skull and partial skeleton of *Mesosuchus browni*, Watson. This paper contains the description of the only known complete skull of *Mesosuchus browni* from the Cynognathus beds of Aliwal North, as well as of the front half of the skeleton. The relationships of the form with Youngina, the Sphenodontia, the Rhynchosauria, the Lizards, Howesia, and the Thallatosauria, are discussed, and it is concluded that Mesosuchus may be placed in a new family, which is called the Mesosuchidæ, and placed in a new sub-order of Diapsid reptiles, the Mesosuchia.—C. W. **Kops**: A South African life table based on the European male population census. (Communicated by Prof. J. P. Dalton.) The life table is based on the census returns of 1918 and 1921, and the deaths during the years 1919–1921. The function graduated is $q_{\bar{x}}$. The graduation was performed by fitting three curves to the data—a quadratic, together with an exponential function for ages 0 to 15, a first degree function, together with an exponential for ages 24 to 108, and these curves are joined by a cubic function having first order contact with each of the other curves. A Makeham graduation was also applied from age 20 to the end of the table. Both graduations are then compared with standard tables from other countries. Graphical comparisons are also made in the case of each graduation.

ROME.

Royal Academy of the Lincei, May 18.—B. **Grassi**: The transmission of malaria. In some years marked discordance exists between the number of Anopheles and the intensity of the malarial epidemic, the number of malarial individuals at the outbreak of the epidemic being insufficient to justify such discordance. The amount of semilunar gametes in some localities appears inadequate to explain the epidemiology of this form of malaria, except on the supposition of a mutation of the tertian parasites or a hybridisation of the latter with the estivo-autumnal parasites. A general incongruity is observed between the abundance of the gametes and the new infections, the gametes abounding particularly in winter and spring during which seasons the Anopheles has no opportunity of undergoing infection.—A. **Russo**: Mixed individuals formed from the ex-conjugants, after true conjugation in *Criptochilum echini* Maupas, and the origin of the gametogens. These mixed individuals are shown to be differently constituted, not only from the diverse origin of the nuclei composing their nuclear apparatus, but also as regards the quantity of nuclear substance present. Of the four nuclei which go to make up this nuclear apparatus, one only assumes the sexual function for the formation of gametes.—G. **Vranceanu**: Stability of rolling of a disc.—M. **Maggini**: Distribution of the radiating power on planetary discs, determined with the interferometer. Investigation of the distribution of luminous intensity on the apparent discs of the planets Uranus and Vesta shows that, as is the case with Jupiter and Saturn, the peripheral regions are less luminous than the central ones.—F. **Signore**: Temperature measurements made in Lake Lucrino and in the neighbourhood of Maricello during 1922–1923.—G. **Piccardi**: Further observations on a thermal method for the study of gaseous systems. Experiments on a number of the more permanent gases by means of the apparatus now described give results in satisfactory agreement with the theory previously advanced.—G. R. **Levi** and A. **Ferrari**: Crystalline lattices of magnesium hydroxide and carbonate. The fundamental element of magnesium hydroxide is a parallelopiped having a rhombic base of side 3·114 Å and an acute angle of 60°, the height being 4·735 Å. The corresponding density would be 2·40, which agrees perfectly with the actual values for the natural and artificial products.—O. **Munerati**: Artificial nocturnal illumination as a means of accelerating the phases of the vegetable cycle.—R. **Perotti** and F. **Aureli**: Ammonifying power of arable soil. The method of measuring the ammonifying power of soils by means of nutrient solutions reveals marked differences corresponding with those found in the condition of the vegetation of the soils. With "normal" soils, which exhibit an alkaline reaction, the aptitude to the micro-biochemical production of ammoniacal nitrogen usually suffices for the needs of vegetation.—R. **Perotti** and G. **Grandis**: Measurement of the nitrifying power of arable soil. The optimum conditions for the measurement of the nitrifying power of soil by the method of nutrient solutions are defined.—P. **Dorello**: Observations on the erectile body of the penis of the genus Helix.—A. **Busacca**: Structure of the living crystalline fibre. The protoplasm of the fibre of the crystalline lens exhibits formations of undoubted mitochondrial character. These formations being mobile, the fundamental substance of this protoplasm is not a solid hydrogel but one of some fluidity, the latter resulting from the high degree of

bibition experienced during the development. though it has undergone very marked differentiation, the protoplasm preserves unchanged all the tributes of true protoplasm and cannot be regarded a metaplasmatic substance.—E. **Momigliano**: Behaviour of lipoids in nephropathy.

Vienna.

Academy of Sciences, March 6.—F. **Reinitzer**: Researches on olive-resin.—R. **Weiss** and E. **Freund**: The action of organic magnesium compounds on phthalonitril, I.—G. **Weissenberger** and L. **Piatti**: The behaviour of creosole towards alcohol, ether, and acetone.—V. **Brehm**: Diagnoses of new Entomostraca, part III. Report from the Handel-Mazetti Expedition to China, 1914–1918, supported by a grant from the Vienna Academy of Science. New species are, *Diaptomus bidens*, Yunnan, and *D. Walterianus*, Yunnan.—G. **Jager**: The lines of force in the special theory of relativity.

March 13.—F. **Feigl** and A. F. **Lederer**: On diphenylcarbazon and its salts, also on the supposed diphenylcarbodiazon.—J. **Krames**: Regular surfaces of the third order, the infinite curves of which doubly osculate the absolute conic section.

March 20.—K. **Mader**: On the use of the Eötvös balance with large masses at close distances.—E. **Müller**: A new method for combined measurements of the capillary constant and of the internal friction of viscous liquids.

April 3.—E. **Heinricher**: Sleeping reactions of the inflorescences of *Dimorphothera pluvialis* (L.). The principal factor in the sleeping reactions of *Dimorphothera pluvialis* is change of temperature.—D. **Pettersson**: On the maximum range of the particles discharged from radium C (Mitt. d. Ra-Inst's No. 163). The long-range particles assumed by Bates and Rogers to be discharged from radium C have been examined under conditions excluding the production of secondary particles. The number of particles of ranges exceeding that of the normal α-particles was found to be less than a few per cent. of the number found by these authors.—E. **Landau**: On the inapplicability of Pfeiffer's method in the analytic theory of numbers.—R. **Weiss** and J. **Korczyn**: (Trimethylene-triphenylmethane-triketon).—A. **Merz**: Investigations of elastic after-effects by an acoustic method.—M. **Eisler** and J. **Portheim**: On insulin-like substances and their action on the exchange of the carbo-hydrates (Preliminary communication). Production of an insulin like substance from seeds of *Phaseolus multiflorus*, and preliminary experiments on the influence of this substance on the exchange of carbo-hydrates in the plants.—I. **Robinsohn**: The colouring of the stigmata—Stigmatochromy. A morphologic-biological method for researches on flowers.—H. **Handel-Mazzetti**: Plantæ novæ Sinenses diagnosibus brevibus descriptæ.—Fuller Abstracts for the Vienna Academy of Sciences in 1923 are given in *Die Naturwissenschaften* for May 9 and May 16, pp. 372 and 394. These contain earlier papers on Triton by Weiss, on meteorology by Exner, and on cave-bears by Abel and others.

May 8.—Alois **Zinke** and Franz **Hanselmeyer**: Researches on perylene and its derivatives (Communication VI).—Alfred **Wagenhofen**: Contributions to our knowledge of para-orsellinic-acids. The aim of the work was the verification of the influence of the methyl-group on the retention of the carboxyl-group in many-substituted benzoic acids, for which the para-orsellinic-acid was chosen as starting-point. The nitrification of the dimethyl-para-orsellinic-acid-methyl-ester led to a mono-nitro-substitution product.—Elisabeth **Kara-Michailova** and Hans **Pettersson**: Communication of the Radium Institute, No. 164. On the measurement of the relative brilliancy of scintillations. A method is described for the determination of the relative brilliancy of scintillations and of their application for a confirmation of the particles deviating from quartz under α-particle bombardment as H-particles.—Anton **Kailan** and Roman **Obogi**: On the question of purifying glycerine from volatile fatty-acids and their esters. The addition of alkali works prejudicially on the distillation of glycerine, since it does not diminish, or does not appreciably diminish, the acid figure in the chief fraction whilst the ester figure is very strongly increased.—Kasimir **Atynski**: The preparation of selenides from selenium hydride and metallic salt solutions. The selenides are appreciably less stable than the sulphides.

May 14.—P. **Flach**: Cytological researches on vessel formation in *Cucurbita Pepo*.—Frau Dr. Helene **Kurz**: *Pholidopus* (*Achtheinus*) *intermedius* and *Dissonus glaber*, two new species of the family Caligidæ.

Washington, D.C.

National Academy of Sciences (Proc. Vol. 10, No. 6, June).—W. M. **Davis**: The formation of the Lesser Antilles. The banks on which the Lesser Antilles stand represent reef-enclosed lagoon floors, formed according to Darwin's theory of coral reefs and modified by the processes of the glacial-control theory. The scheme of development is as follows. First there is eruptive growth of a volcanic island on a subsiding foundation; subsidence continues after growth ceases and lagoon deposits increase within the up-growing barrier reef. Reef abrasion and headland cliffing occur whenever the Glacial period intervenes. The second cycle commences by upheaval or uptilting and may interrupt the first cycle at any stage. Some of the Lesser Antilles are first stage islands and some belong to the second period.—G. R. **Putnam**: Radio fog signals for the protection of navigation; recent progress. The radio compass is considered to be the most important instrument invented for use on shipboard since the introduction of the magnetic compass. It is used in conjunction with radio fog signals which, in the United States, consist of characteristic signals on a wave-length of 1000 metres. There are 11 such beacons in the United States waters and 12 outside. About 291 vessels now have radio-compasses or direction finding apparatus. The spark transmitters are to be replaced by tube transmitters. With the present apparatus and conditions of use, no serious error is caused by the "night" effect.—D. F. **Jones**: Selective fertilisation among the gametes from the same individuals. Pollen carrying a dominant factor is better able to accomplish fertilisation in a sporophyte carrying the same factor than pollen carrying the corresponding recessive factor.—W. E. **Castle**: The Japanese rabbit and gametic purity. The so-called "Japanese" rabbit is yellow, mottled or brindled with black. The brindling seems to depend on the formation of a mosaic type of gene, very rare in occurrence but very stable when once produced, which is due to imperfect segregation between black and yellow, themselves simple allelomorphs.—K. **Sax**: The nature of size inheritance. Experiments with beans show that differences in size and total yield are, to some extent, due to factors linked with qualitative factors which are subject to Mendelian inheritance. Analysing Castle's rabbit data by determining partial correlations with body weight held constant, it is concluded that Castle is correct in stating that the genetic agencies affecting size in rabbits are general in action. The data of other workers using different animals indicate that body proportions may not be entirely dependent on factors which affect body weight.—E. B. **Wilson** and W. J. **Luyten**: A statistical discussion of sets of precise astronomical measurements. II—

Proper motions. Allegheny and McCormick Observatories issue photographic proper motions in Right Ascension with reference to the mean of the comparison stars. The values are compared with meridian circle determinations (Boss), from which it appears probable that a factor of about 1·4 should be applied to the probable errors.—Raymond **Pearl**: The influence of alcohol on duration of life. Accurate information has been collected for a group of more than 6000 white persons of a working-class population. Exhaustive data were obtained and the material classified in eight groups according to alcohol consumption. Calculation of life-tables and so on shows that at every age from 30 to 100, moderate drinkers of both sexes have a slightly *higher* expectation of life than abstainers. Male heavy drinkers have a markedly lower expectation of life than moderate drinkers from 30 to 100 and than abstainers from 30 to 60; from 60 onwards the advantage is slightly to the heavy drinkers, possibly due to the selective effect of high mortality among heavy drinkers prior to 60. For females, expectation of life is markedly lower for heavy drinkers than for moderate drinkers or abstainers from 30 to 100.—W. M. **Wheeler**: Two extraordinary larval Myrmecophiles from Panama. Both were found in ant nests. One is broad, regularly elliptical, 5·7 mm. long, with flattened creeping-sole bordered with minute red papillæ; the integument is smooth, pale blue, and bears regular longitudinal white scales which on pupation were thrown violently off. No imaginal fly was obtained. It has been named *Microdon æolidiformis*. The other form has an anterior portion which can be withdrawn into the carapace-like abdominal region. The latter is covered with a mosaic of regular hexagonal chitinous plates, the dorsal surface bearing regularly arranged sense-organs; there is no creeping-sole. It has been named *Nothomicrodon aztecarum*.—W. B. **Cannon** and A. **Querido**: The rôle of adrenal secretion in the chemical control of body temperature. The rate of heart beat in animals with denervated hearts was increased 12 to 64 per cent. by cooling the body. The effect is not obtained if the adrenal glands are made inactive though shivering is still produced. It is argued that increased adrenal secretion can augment metabolism to counteract the effects of cold.—W. B. **Cannon** and J. R. **Pereira**: Increase of adrenal secretion in fever. Experiments similar to those of the previous paper show that fever is associated with increased adrenal secretion.—E. W. **Brown**: An explanation of the gaps in the distribution of the asteroids according to their periods of vibration. Instability of motion is suggested, on a mathematical basis, as the cause of the gaps.—J. H. **Oort** (1) Note on the difference in velocity between absolutely bright and faint stars. For stars with total velocities less than 65 km. or for stars moving in a direction opposite to the motions of high velocity stars, the average velocities for giants and dwarfs are nearly equal. There is no hint of increase of velocity with decreasing mass. (2) On a possible relation between globular clusters and stars of high velocity. Curves showing the galactic distribution of globular clusters and the antapices of the motions of high velocities alike show marked avoidance of the Milky Way.—W. J. **Luyten**: Note on some statistical consequences of the luminosity law.—W. C. **Rufus**: Atmospheric pulsation of the Cepheid variable, η Aquilæ. Line displacements from different elements and at different levels of the atmosphere of a star have been studied. Generally, compression of the atmosphere occurs after maximum compression of the star as a whole, thus accounting for the retardation of the light maximum. The humps of the velocity-difference curves of the various layers are synchronous with the *Stillstand* of the light curve; the latter appears to be due to a stage of comparat rest in the star's atmosphere.—B. de **Kerékjárt** On parametric representations of continuous surfac —A. H. **Compton** and Y. H. **Woo**: The wave-len of molybdenum Kα rays when scattered by li elements. The secondary radiators used were lithiu boron, carbon, water, sodium, magnesium, and a minium, and in every case, after scattering at abo 125°, an addition to the usual Kα peak, there w another in the position predicted by Compto quantum theory of scattering. With sodium a aluminium, there is perhaps some evidence of tertia scattering in accordance with the theory of Cla Stifler, and Duane.—E. C. **Kemble**: Quantisation space and the relative intensities of the components infra-red absorption bands. Bohr's corresponde principle applied to the evaluation of the intensities lines in the infra-red absorption bands of diatomic ga gives values contrary to experiment in the case of t hydrogen chloride band at 3·5 μ. Better results a obtained by assuming a slight precession of the orbi plane about the lines of the earth's magnetic field. L. **Thompson**: The ballistic (air resistance) functio —W. A. **Setchell**: Ruppia and its environmen factors. Two distinct forms of *Ruppia maritima* were found at Richardson Bay, California. stations subject to tidal conditions, the plants w perennials with long, spirally curved peduncles, a most of the fruits were robust, rounded and only sligh curved without pronounced beak (var. *longipe* Plants growing in shallow pools were annuals wi practically opposite characteristics (var. *rostrat* Laboratory experiments show that both variet tolerate a wide range of salinity, P_H and dayligh darkness ratio; temperatures of 15-20° C. are nec sary for germination, and 20-25° C. for growth a reproductive activity.

Problems of the Coal Mining Industry.

WHEN Mr. Lloyd George was in power about 1919, various proposals relating to the mining industry were put forward by him; and it may be remembered that they were rejected successively by all the interested parties. The essential points of these proposals have now been re-stated in a report entitled "Coal and Power,"[1] just issued as a slender volume. We are not concerned here with the political aspect of Mr. Lloyd George's suggestions, but it may be worth while to consider the technical and economic sides. As regards coal mining, the suggestions fall into two main groups, namely :

1. The acquisition by the State of mineral royalties. (Incidentally it may be noted that the authors of the report have not decided how far they should go in this respect; in the introduction, the summary of the proposals suggests "purchase of all minerals and royalties by the State," whereas in the body of the report we find the following sentence : "Further, it is to be considered whether the State, when acquiring its coal resources, should at the same time acquire all the mineral resources of the country." Surely the author or authors of this report ought first to have made up their minds as to what they really want to do.)

2. The formation of consultative bodies consisting of miners and mine owners, who are apparently to discuss the problems of the industry. (Throughout, the author or authors of the report overlook the importance of the mining engineer and the mine manager; whenever the technical staff is casually referred to, it is looked upon as part and parcel of the mine ownership; any discussion of the future of the industry that fails to recognise that there are at least three separate bodies to be considered, namely, miners, mine owners, and technologists, must necessarily be imperfect.)

The report examines at some length the reasons for the present disturbed state of the industry, but fails to recognise one of the most serious. A small but active section of the miners' leaders appears to have determined to get the whole of the coal mining industry into its own hands, an operation which these men designate as nationalisation, and apparently they have come to the conclusion that the best way of attaining their object would be to wreck the industry as it now exists.

It is pointed out quite clearly in the report that nationalisation of the coal resources is a matter which can legitimately be undertaken by the State, whereas the nationalisation of the industry cannot. It is well known that there are two forms of mineral ownership. In one, which is adopted by most Conti-

[1] Coal and Power: the Report of an Enquiry presided over by the Rt. Hon. D. Lloyd George. Pp. xiv+139+16 plates. (London: Hodder and Stoughton, 1924.) 1s. net.

nental nations, the State owns the minerals and leases them to the mine owners; in Great Britain and the United States, the minerals are the property of individuals who may deal with these minerals as they see fit. Both systems operate and operate successfully, but it is a curious fact that the two countries where the minerals are privately owned are those where mining has reached its highest pitch of development, and, incidentally, where the miners' wages are the highest. The present report proposes to purchase the coal royalties, and shows a series of advantages which it claims would result from such change of ownership. Curiously enough, not a word is said about the fact that the Crown already owns quite important mineral areas; for example, it owns all the under-sea coal, and it owns practically all the coal in the Forest of Dean Coalfield. This State-owned coal, however, is leased and dealt with in precisely the same way as the privately-owned coal in the country, and none of the advantages which are claimed for the State ownership of minerals are apparent in the quite considerable tracts of State-owned coal already in existence. Incidentally it may be pointed out that wages in the Forest of Dean coalfield are about the lowest in the whole country.

No reference is made in this report to the very important lessons to be learnt from the United States. In the United States the minerals were originally the property of the State, and at first the Federal Government attempted to lease its minerals, but after something like half a century of experimenting on these lines it was found far better to get the mineral lands as soon as possible into private hands. The author or authors of this report might study with advantage the evidence given by Dr. R. W. Raymond before the 1889 Royal Commission on Mining Royalties upon the methods adopted in the United States. One sentence alone from his evidence may be repeated here: "I have been accustomed to say at home over and over again that it would be better for the United States to-morrow to give up all its mineral land and deliberately convey it to individuals for nothing in order to have somebody own it instead of the Government." In the face of such an emphatic pronouncement, based upon experience, it would surely appear to be a risky experiment to desire to revert in Great Britain to the method of State ownership of royalties. It may be freely admitted that the method is quite workable, seeing that it is in operation in most Continental countries, but there is no evidence that any advantage would accrue from it.

Another point which is emphasised in the report before us is the possibility, if all the minerals were State-owned, of doing away with barriers. Any experienced coal miner knows that some barriers are indispensable for the safety of the mines; the repo also overlooks the fact that power to have unnecessa barriers removed is given under the Mines (Worki Facilities and Support) Act 1923, but so far not single application for the removal of barriers und this Act has yet been made, which shows that the ev if it exists at all, is certainly not a very pressing one

The method suggested for the purchase of royalti is to divide all minerals into three classes, those whic are known to exist and are actually under lease, tho the existence of which is highly probable althoug they are not actually under lease, and those as to th existence of which nothing definite is known. It proposed to deal forthwith only with the first name of these, and that they should be purchased for bon issued by the Treasury, bearing interest, the rate which the report conveniently omits to give. It stated, though no basis of calculation is given, tha the actual value of these minerals is approximatel 70,000,000*l*. The total known coal reserves of Gre Britain have been estimated at something like 150,0 million tons; assuming an average coal output 300 million tons, the coal reserves would give a li of 500 years. For actuarial purposes this may b looked upon as a perpetuity, and the calculation i this way simplified. The amount of royalties pai on coal in 1923 was 6,300,000*l*., so that unles royalty owners are to be deprived of a portion of the income, these bonds ought to bear 9 per cent. interes These points are not considered in the report.

The second suggestion, which again is by no mean fully worked out, is to appoint a series of bodies whic are apparently to take a sort of paternal consultativ interest in the mining industry. It is proposed t have three bodies, a National Mining Council to dea with the industry as a whole, District Boards fo dealing with questions in each individual district and Pit Committees to be "established in connexio with every pit, to consist of equal numbers represent ing the management and the workers." The repor does not make it clear whether "pit" committee i meant or not. There are individual colliery companie having a dozen different pits; is it suggested tha there shall be such a committee for each one of thes pits? The idea of pit committees was decisivel rejected by both the miners and the mine owners and rightly so. The first essential for the safe an economic administration of a colliery is strict disciplin throughout the pit, and it is obvious that there woul be an end of such discipline if every petty questio that arose had to be referred to a pit committee, whil practical men do not need to be told that, in everyda colliery working, problems arise which must be deal with on the spot and cannot be left to stand ove

r discussion in a fortnight's time by the pit committee. istrict boards would probably do no harm, and a ational Mining Council would probably be quite eful. Indeed, something approximating to this ready exists in the Advisory Committee of the Mines epartment.

A detailed discussion of all the statements in this port would demand far more space than is here ailable; the reader not versed in colliery matters ould, however, be warned not to take all that he ds here as gospel truth, an unfairly coloured picture ing presented in many cases, Thus to take e example, a number of photographs of miners' uses are shown, obviously with the intention of citing the reader's sympathy. Three of these are a block of cottages at Leadgate in Co. Durham. a matter of fact, these cottages are now being pulled wn by the colliery company which owns them in der to be replaced by more modern accommodation; rely the writer of the report ought to have known is fact, and if he knew it he ought surely to have ated it! It is difficult to understand how any one o knows the miner at all can write such a sentence this: "Habituated with the conditions he (the iner) is not impressed with the imminence of danger, t he is aware of it; it is at the back of his mind always d affects his outlook on life." The miner rarely thinks danger when he goes to his daily work, and would obably feel deeply insulted if any one suggested to m that he did. A couple of Durham pitmen who had en called up to London to give evidence in conxion with a mining case were heard on their return be congratulating each other on being once again fe down the pit and away from the dangers of the ndon streets, and this represents the true attitude the miner towards his daily occupation. As a matter fact, their estimate of comparative danger was not ally so far off the mark, seeing that there were *two-nd-a-half times* as many fatal accidents (in 1922) in e streets as there were in the collieries of Great itain. Great play is usually made in the discussion coal mining, especially by those who are ignorant the subject, with the dangers supposed to attend is work. It is unquestionably one of the more ngerous occupations, but its dangers are immensely ggerated, and it may be hoped that the above mple statement of fact may help to put the problem its proper perspective.

It need scarcely be said that there is only one real medy for the difficulties with which the coal industry struggling to-day, and that one, being unpalatable, many salutary remedies are, is never mentioned the report. It is summed up in the two words "MORE WORK."

H. LOUIS.

Theories of Growth and Senescence.

The Chemical Basis of Growth and Senescence. By Prof. T. Brailsford Robertson. (Monographs on Experimental Biology.) Pp. viii+389. (Philadelphia and London: J. B. Lippincott Co., 1923.) 12*s.* 6*d.* net.

THE physicist who theorises is more fortunate than the biologist. He may elaborate theoretical considerations for the whole of his life and still be talking sense at the end of it. It is hard for the biologist to theorise for five minutes without talking nonsense. Yet biologists, in spite of all the warnings of the past, find the theoretical impulse irresistible, and sometimes it is useful for them to give way to it. Not that their theories are likely to be true, but that they usually raise such acute opposition on the part of other biologists that the others devise experiments to refute them, and much valuable information is obtained. Not all theories have this salutary effect. Some act as intellectual soporifics providing attractive names, the frequent repetition of which hypnotises the hearers and stops all further inquiry. Of all the words that possess this "virtus dormitiva," there has been none greater than Weismann's "germ plasm." The "germ plasm," so far as we understand it, is a hypothetical substance with magical properties, which exists in living cells and enables them to divide. Some of it is infinitely divisible, and the possessors of this sort are germ cells; some of it resembles ordinary matter in being finitely divisible, and cells that possess this sort are somatic cells. Perhaps this statement is erroneous and the theory is not quite so bad really, but if so the difference is too subtle to have been grasped by its adherents or opponents.

Prof. Robertson's own theories are of the beneficent type just mentioned, but he has the misfortune to be haunted by the germ plasm, and at times the incubus is demoralising. The main theory which he advocates in this book is definite and capable of being put to experimental test. If it does not agree with all the facts, that is not surprising in the present state of knowledge. We may legitimately applaud Prof. Robertson for having found a theory which accounts for any of the facts, without therefore being expected to believe in it or to refrain from criticising it.

The fundamental facts on which the theory is based are, in brief, that the rate of growth of animals and plants follows a logarithmic formula that is the formula for the progress of an autocatalysed chemical reaction. Among the mammalia three growth cycles can be distinguished. Where, as in man, the cycles are definitely separated, the formulæ for each cycle show excellent agreement with the average curves of growth. In

some animals the cycles overlap and the results are therefore not so clear cut. On the assumption that growth is essentially an autocatalysed reaction, or rather that a reaction of this kind regulates its rate of progress, and assuming also that the autocatalyst concerned has certain special properties, the author proceeds to explain a large number of facts concerning differentiation of structure, regeneration, senescence, and so on. Let us first consider the significance of the growth curve itself.

The rate of growth of an organism, measured as increase in mass per unit time, first of all increases and then diminishes, giving a symmetrical S-shaped curve. This curve might be obtained either if we had an autocatalysed monomolecular reaction which came to a stop by the exhaustion of the material undergoing change, or if the reaction was reversible with both forward and backward reaction behaving as monomolecular, while the material supplying the forward reaction was maintained at a constant concentration. The second alternative is the one Prof. Robertson considers most probable, because in most organisms the supply of nutrient material for the cells is kept constant and the growth of animals certainly does not come to a stop at maturity for lack of nourishment. From the chemical point of view, there are two chief criticisms to be made to this theory. In the first place, it appears to be assumed that the reactions concerned in growth are all going on in homogeneous solution ; an assumption that is not at all probable. The materials used for cell synthesis are certainly in aqueous solution, but some at least of the final products are not.

To this criticism Prof. Robertson would probably reply that whatever the nature of other chemical reactions concerned with growth, the particular one he is interested in occurs in homogeneous solution. Indeed, for the purposes of his theory he assumes that the autocatalyst itself, which must be a synthetic product, is diffusible and can pass from the cells to the body fluids, and therefore is likely to be in solution. If this be so, there is a further and more damaging argument to bring up.

All known processes of synthesis of organic cell constituents from organic food materials are processes of "condensation"; they consist in the elimination of the elements of water from between two or more molecules ; and the reverse process is a hydrolysis. According to Prof. Robertson's own statement (p. 14) his autocatalysed reaction is likely to be of this type, because the only reverse reactions that could behave as monomolecular are oxidations and hydrolyses. As the animal body does not synthesise by reduction, the reactions must consist of condensation and hydrolysis respectively. On his view, however, they must go on in aqueous solution. The chief cell constituents, proteins, po saccharides, fats and lipins, can all be shown to be u stable in the presence of water at the reaction of livi tissues. The position of equilibrium is one of almo complete hydrolysis ; this can be demonstrated by t action of the common hydrolysing enzymes. The fore, cell synthesis must either take place in a no aqueous medium, or else by some process not rep ducible in the laboratory that carries a reaction aw from the equilibrium position, against the therm dynamic gradient as it were. In either case the sim laws of catalysis in homogeneous solution are n applicable.

It is possible to imagine some soluble diffusi material being produced as a by-product of c synthesis and acting as a catalyst of further synthes but it is almost impossible to see how such a substa could control the rate of growth in the way that Pr Robertson supposes. What plausibility his hypothe possesses at first sight, vanishes when any atten is made to describe in detail from the physi point of view how an autocatalyst of growth wo operate.

The autocatalyst of growth is supposed to be pres in the body fluids, and its concentration there is s posed, among other factors, to regulate the rate growth, accelerating it at first, and later, as it accur lates, bringing growth to an end. If this be the case, th blood from an adult animal ought to stop the grow of the tissues of a growing animal, and repeated bleed of an adult animal with replacement of the blood washed blood corpuscles in a suitable artificial medi might be expected to start growth again. Rec experiments by Carrel and Ebeling (*C.R. Soc. Bi* 1924, vol. 90, p. 170) suggest that the blood of you and of old animals differs in some such way, thou the results are not exactly what Prof. Robertso theory would lead us to expect. Moreover, if the the is correct, it must be supposed that the placen membranes alone among tissues are impermeable the autocatalyst, otherwise the mammalian emb would never grow.

The evidence that the autocatalyst is soluble a diffusible is based, not upon any evidence from t higher animals, but solely on studies of infuso bacteria, and yeasts. In cultivating these organis it has frequently been observed that multiplication stimulated by some dissolved substance which resu from the presence of other organisms. (It is a p that in this connexion Prof. Robertson makes reference to the important work of Dr. E. J. Allen the growth of marine algæ (Jour. Marine Biol. Asso vol. 10, 1914, p. 417).) The growth-stimulating su stance appears to be common to several different typ

organism, but it is rather rash to assume on his account alone that an exact parallel can be drawn between the culture medium in which infusion organisms live and the body fluids of the higher animals.

There is no direct evidence on this point as to the higher animals, but some indirect evidence that goes strongly against this assumption. In their powers of chemical synthesis, living things seem to fall into three well-marked groups—the green plants, the "infusion organisms," and the higher animals. At the one extreme the green plants can synthesise all their body material from inorganic sources; at the other the higher animals, who have specialised in a different direction, have very largely delegated the business of synthetic organic chemistry to humbler creatures on whom they feed. The mammalia, for example, cannot synthesise the benzene or indole ring, but have to get them ready made in their food. The infusion organisms, such as yeasts, ciliate protozoa, and probably bacteria, moulds and other saprophytic plants, occupy an intermediate position rather nearer to the green plants than to the higher animals. They cannot live without ready formed organic material, as the green plants can, but they only need comparatively simple carbon compounds. Ciliate protozoa, as Prof. R. A. Peters has shown, besides inorganic salts, need only ammonia and an organic substance, such as lactic acid or glycerol, with a chain of three carbon atoms (*Jour. Physiol.*, vol. 55, 1921, p. 1). When the chemical processes underlying processes of growth are so different in the two groups, sweeping analogies appear to be out of place.

Prof. Robertson embodies in his theory certain subsidiary hypotheses, namely: (1) That growth is regulated by the cell nucleus in which the autocatalyst is found; (2) that it is only during mitosis that the autocatalyst escapes into the cytoplasm and body fluids; (3) that, in any given cell, division is regulated by the relative volumes of nucleus and cytoplasm; (4) that in the life-history of somatic cells there is a progressive change, a process of senescence, whereby the nuclear-cytoplasmic ratio at which division can take place gets smaller and smaller. The last change is supposed to be irreversible, and it is there that the trail of the germ plasm becomes evident. These hypotheses are, to say the least, not very firmly grounded on fact, and it is doubtful whether they increase or diminish the plausibility of the theory as a whole. They do, however, enable the author to give a detailed, if fanciful, explanation of the process of senescence and of phenomena such as the growth of cancer cells.

Leaving these questions aside, let us consider how the author deals with the facts of regeneration of lost or injured parts, for they are likely to prove crucial for any theory which partakes of Weismannism. Although there is considerable discussion about regeneration in the book, it is not easy to find a precise statement as to how the process is supposed to come about, but we get some information on p. 264. The view apparently is that in the adult organism cell division stops because of the accumulation of autocatalyst, but the stoppage is only relative to a given concentration of nutrient materials, so that anything which raises the concentration of nutrient material may start cell division going again. Injury is supposed, by removing competing cells, to cause a local increase of nutrient material, which acts as the stimulus for proliferation. Once the cells have started dividing, the rest of the process is explained in terms of nuclear-cytoplasmic ratios.

This part of the question need not concern us at present, except to point out that regeneration must, on Prof. Robertson's theory, be an irreversible process of senescence and therefore not capable of indefinite repetition. The really startling part of the theory is the suggestion that it is a local increase of nutrient material which first stimulates growth after injury. It must be confessed that no alternative theory is forthcoming, but one is not compelled to accept a false theory because there is no other to put in its place. When a lizard drops its tail there cannot be more than a momentary increase in the nutrient materials in the blood and body fluids, and what increase there may be will be quickly equalised all over the body. Suppose there is an increase that provides the stimulus to cell division, why does growth take place only at the stump and not throughout the whole of the animal?

The regeneration of a lost part is not the result of simple division of the functional cells *in situ*, but is the work of special cells which are in appearance embryonic. These cells appear to arise by de-differentiation of some of the cells of the region of growth. Thus it is found that the lizard's tail is regenerated by embryonic cells in the stump which persist at the growing end, until a tail which is functionally equivalent to the original has been produced. But structurally the new tail is not altogether similar. Bone is not regenerated, but cartilage takes its place and there are no new nerve cells. The new tail is innervated by nerve fibres growing out from some of the intact segments of the spinal cord. (See Dr. C. Powell White, British Assoc. Report, 1915, p. 472; more detailed information is in course of publication by the same author.) Another fact to be kept in mind is that many of the invertebrates can regenerate lost parts an indefinite number of times.

These facts show that the ordinary progression from youth to age can be reversed under certain conditions by some of the somatic cells. Immortality and rejuvenation are not a prerogative of the germ cells only. Somatic cells can, in many cases, take on the functions of germ cells by giving up their special function and reverting to a younger type. This fact has been notorious among the green plants, but it is also evident among the animals, even among the vertebrates. Any remnant of the germ plasm theory, however attenuated, is directly contradicted by these facts. One seems to be driven to take up some sort of position akin to Prof. C. M. Child's, who considers growth, senescence, and rejuvenescence in terms of the metabolic activity of the cells and not in terms of their visible structure or of hypothetical invisible components. One of the defects of Prof. Robertson's book is that he never once mentions Child's theory though referring several times to Child's experiments. In politics it may be often advisable to treat opponents with silent contempt, but men of science are expected to demonstrate the falsity of other theories before establishing their own.

Unworkable as Prof. Robertson's theory is in its present state, it has the merit of emphasising certain important facts which have got to be explained somehow or other. Apart from germ plasm complications, which are really extraneous to the main part of his views, the definiteness of the theory that makes it possible to subject it to experimental test is a great merit.

There is one final point of criticism that is perhaps worth making, though it concerns something outside the author's main line of argument. In the final chapter, in which general questions of evolution are discussed, the statement that variation always takes place by loss of characters reappears once again. It is quite true that under domestication the vast majority of heritable variations that have been observed, both in animals and plants, consist of the loss of a Mendelian factor. But it is also true that the conditions of domestication are physiologically peculiar and that the observed variations do not resemble the type of difference that normally distinguishes wild species from one another. Finally, there are a few cases among domestic animals that cannot be attributed to any cause other than the gain of a Mendelian factor: the most familiar of these are the White Leghorn plumage, and the Rose and Pea Comb among fowls. These are all dominant to the wild type, which in this species can be identified. That variation by gain of Mendelian factors occurs but rarely is no reason for denying its existence.

Rockets to reach Planetary Space.

Die Rakete zu den Planetenräumen. Von Herman Oberth. Pp. 92+2 Tafeln. (München und Berlin: R. Oldenbourg, 1923.) 1*s.* 6*d.*

THE prospect of propelling a body from our earth to one of the heavenly bodies, notably the moon, has excited certain types of individuals for some time, and many romances have been built up round the idea. Scientific attention has been given to the matter in recent years, and in particular Prof. Goddard of Clark University, in the United States, has examined the question theoretically and experimentally. His plan is to send a rocket to the moon, more or less as suggested by Jules Verne, with the important difference that the rocket is not to be left to the mercies of air resistance and gravitational forces, but is to be propelled continuously by means of firing successive charges of smokeless nitrocellulose. Herr Oberth claims to have obtained the results given in the present volume quite independently of Prof. Goddard. He says that he commenced working at the problem in 1907, and that the main ideas were evolved in 1909; the calculations and proposals of this book were made during the years 1920–22.

Herr Oberth is more ambitious than Prof. Goddard; his object is to obtain sufficient financial support to be able to send off a rocket large enough to hold human beings. For fuel he suggests liquid hydrogen and a mixture of water and alcohol, the liberated gases escaping through small holes at the back of the rocket and thus forcing the rocket forwards. He calculates that an initial speed of 11 km./sec. would suffice for getting out of the earth's field of gravitation. The calculations are simplified by introducing the assumption that while the rocket is still in the earth's atmosphere, the fuel is used at such a rate as to give at each instant what is practically the "limiting velocity" at the instant.

The author discusses the theoretical as well as the chemical, physical, and even physiological aspects of such a venture. He examines the economic possibilities, but he does not appear to be very sanguine about his scheme being carried out. He estimates that a rocket for two persons would weigh 400 tons, would need 25 tons of alcohol and 4 tons of liquid hydrogen and would require an initial outlay of 50,000*l.* on the basis of pre-War prices.

A voyage to the moon would be an attractive trip to many adventurous spirits; and in these days of unprecedented achievements one cannot venture to suggest that even Herr Oberth's ambitious scheme may not be realised before the human race is extinct.

Our Bookshelf.

Handbuch der Zoologie: eine Naturgeschichte der Stämme des Tierreiches. Begründet von Prof. Dr. Willy Kükenthal. Herausgegeben von Dr. Thilo Krumbach. Band 1: Protozoa, Porifera, Coelenterata, Mesozoa. Lieferung 2. Pp. 193-416. 10.50 marks. Lieferung 3. Pp. 417-512. 4.50 marks. (Berlin und Leipzig: Walther de Gruyter und Co., 1923–1924.)

PROF. M. HARTMANN, who is responsible for the account of the Sporozoa, has separated the Amœbosporidia (Neosporidia)—with its two subclasses Cnidosporidia and Acnidosporidia—as one of the six main classes of Protozoa, so that the class Sporozoa now includes only the Gregarinida, Coccidia, and Hæmosporidia. The morphology and life history of the principal members of these orders are carefully described, an outline classification showing the position of the chief genera is given, and a list of the more important memoirs on the subject is appended. The value of the many excellent figures would have been enhanced if the magnifications had been indicated; without these the student is apt to form an exaggerated idea of the size of many of these organisms.

The Ciliophora and the Suctoria are described by Prof. L. Rhumbler.

Prof. E. Hentschel contributes the chapter on Porifera, treated in five orders—Calcarea, Triaxonida (Hexactinellida), Tetraxonida, Cornacuspongia, and Lendroceratida. To compress the account of this large phylum into 100 pages necessitates strict selection of the material available, and no two authors would agree as to the matters to be included, but we would suggest that in the account of reproduction, reference should have been made to the observations of Dendy and Gatenby on the origin of oogonia from collar cells in Clantia, and to Gatenby's account of the peculiar method of transportation of the sperm to the egg.

The third Lieferung is devoted to accounts of the Hydroida and Trachylina by Dr. Hj. Broch and of the Siphonophora (part only) by Dr. Fanny Moser. Dr. Broch gives two maps showing respectively the distribution of some of the marine hydroids and of the Trachylina and freshwater medusæ. The occurrence of Limnocnida in India is not noted here or in the text, though reference is given in the literature list to Annandale's papers on this medusa.

The "Handbuch" is trustworthy, clear, and orderly in its method, and is adequately illustrated with good figures. It provides sound information on the morphology, systematics, development, and ecology; histology, however, is only briefly considered.

The Brain and Golf: Some Hints for Golfers from Modern Mental Science. By C. W. Bailey; and a chapter on Theory and Practice by Bernard Darwin. Pp. xv+96. (London: Mills and Boon, Ltd., 1924.) 2*s.* 6*d.* net.

THE theories of a science often appear to students quite intelligible until it becomes necessary to express them in terms of practical problems; the question of application is always difficult no less in science than in ethics. This little book comes as a welcome relief from the wearisome mass of ill-assorted oddments frequently dignified by the name of applied psychology. It is an amusing, light-hearted account of the laws of physiology and pyschology in so far as they apply to the playing of golf. The game is treated with serious humour; the psychology is not merely appended but is used to explain, to illustrate, to vitalise, the game. The psychologist familiar with the principles and accustomed to applying them in certain fields will find them vivified by their new setting. The golfer will find reasons for many inexplicable troubles and will be taught why such and such a habit is desirable or otherwise; he will be saved much unnecessary depression if he really grasps the laws of habit as here explained, and in particular the reference to the "plateau of habit."

The writer might with advantage have invoked still further the aid of the newer psychology and discussed types of golfers as illustrated by Jung's psychological types, and the revelation that is made of the golfer's own character by his behaviour to superiors, equals, and inferiors on the links. The various "complexes" concerned with the "ego" are more evident than the writer shows, for it is in games that people usually display their fundamental characteristics. A writer of Mr. Bailey's capacity might make a fascinating study of this aspect.

The book can be heartily recommended to all intelligent golfers, to students of psychology, and above all, to those concerned with the application of psychology to education.

A Bibliography of Eugenics. By Prof. Samuel J. Holmes. (University of California Publications in Zoology, vol. 25.) Pp. iv+514. (Berkeley, Cal.: University of California Press, 1924.) 5 dollars.

THE literature of eugenics has grown in a most haphazard way. While the number of scientific journals primarily devoted to the subject is a limited one, yet the medical journals teem with papers having a eugenical bearing, and a widely scattered multitude of books and journals contain information biological, anthropological, psychological, and sociological, which the eugenist must needs consider. There has also been a great amount of popular and semi-popular writing on this subject from widely differing points of view.

It is obviously impracticable to bring an index of all this literature within the covers of one volume. Prof. Holmes has attempted the somewhat more limited task of producing a bibliography which would include all the main sources and items of eugenical literature. In doing so he has produced a volume which will be of great service, not only to students of eugenics but also to all who are concerned with the biological evolution of man. That the field is a modern one is shown by the fact that the great majority of the titles are dated later than 1900, and very few are so early as 1860.

The bibliography is arranged under about 40 different headings, ranging through such topics as heredity and evolution, genealogy, inheritance of deafness, the hereditary factor in crime, the birth rate, the racial influence of religion, the sex ratio, consanguinity, and the selective influence of war. Titles on the inheritance of feeble-mindedness occupy 12 pages of the bibliography. One would like to have seen extended

the sections on the heredity of human traits and human defects. Many additions might have been made here even without encroaching on the medical literature. But although completeness is obviously impossible, and the topics of the author's special interest are naturally emphasised, yet this work will occupy a useful place as a first book of reference on any topic connected with eugenics.

The Road-Books and Itineraries of Great Britain, 1570 to 1850: a Catalogue with an Introduction and a Bibliography. By Sir Herbert George Fordham. Pp. xvi+72. (Cambridge: At the University Press, 1924.) 7*s.* 6*d.* net.

ROAD-BOOKS and itineraries are dear to the heart of the collector, but, unlike most collectors' books, they have a wider interest, and their value to the antiquarian and the topographer is considerable. Many, however, and especially the earlier, are rare and difficult to obtain, and Sir H. G. Fordham's bibliography, which is a revised and amplified reprint of a paper published in the Transactions of the Bibliographical Society in 1916, will be of considerable assistance to those who wish to make use of the material to be found in these guide-books of our ancestors. In this catalogue, road-books are taken to include only such as set out individual roads, with distances and stages all grouped together as a book or atlas, and prepared for the use of travellers. They may vary from a mere enumeration of stages to a full descriptive text. The earliest entry is John Leland's Itinerary published in or about 1535–1543. In the later part of the sixteenth century tables of the principal British highways based on the old British mile of 1500 Roman paces, equivalent to 2428 statute yards, were associated with lists of fairs for commercial purposes. Tables of highways of a similar type were published by Charles Etienne in 1552, while in Germany the earliest would appear to be a publication of 1597, containing 187 roads on the Continent and eleven from London to various parts of England and Wales.

Principles of Electroplating and Electroforming (Electrotyping). By William Blum and George B. Hogaboom. Pp. xii+356. (London: McGraw-Hill Publishing Co., Ltd., 1924.) 20*s.* net.

THE work under notice has been written mainly to help those employed in the industry to understand and apply results which have been obtained in research laboratories. The authors have taken a leading part in the investigation of electrotyping and electroplating processes at the U.S. Bureau of Standards. They divide electrodeposition into four main fields: Electrorefining, electrowinning, electroplating, and electroforming. The last is a new word and is defined as "the production or reproduction of articles by electrodeposition." It is suggested as a substitute for the archaic word "galvanoplasty" which is still sometimes found in text-books.

The very extensive use of iron and steel for constructional purposes, and the fact that they rust when exposed to air, has led to numerous investigations as to the causes and methods of preventing corrosion. Many of the investigations were carried out during the War and the general results obtained were summarised in Circular 80 of the Bureau of Standards. It appears that of all commercial metallic coatings, zinc is much th best protector. It is very desirable that zinc platin should be applied much more extensively in industr than it is at present. Unfortunately zinc coatings hav not a pleasing appearance. When a bright metall lustre is essential, nickel is superior to any other materia This book contains a great many valuable hints and ca be recommended to those technically interested in th subject.

The Growth of Civilization. By W. J. Perry. P viii+224+8 maps. (London: Methuen and Co Ltd., 1924.) 6*s.* net.

IN this volume Mr. Perry restates in a more popul and abbreviated form the arguments put forward at length in his earlier works, "The Megalithic Cultu of Indonesia" and "The Children of the Sun," f the diffusion of culture from one common centr namely Egypt. It forms a companion volume to h book on "The Origin of Magic and Religion," whic indeed is essential for the complete grasp of the arg ment here stated, as in the latter he expounded th theory of the magical influence of gold and oth substances which supplied the motive for the wande ings of the people by whom the "archaic culture was carried to various parts of the world. This boo is, however, not merely a condensation of earlier wor It embodies much evidence not previously considere especially in the later chapters, in which he dea with the coming of the warriors by whom the archa civilisation was overthrown in various parts the world, and discusses the theory that traditio of royal descent from deities derive from contact wi Mediterranean culture and ultimately from Egyp Mr. Perry's statement of what is undoubtedly difficult and highly controversial case, leaves little be desired in point of lucidity.

Faune de France. 7: *Pycnogonides.* Par Prof. E.-L Bouvier. (Fédération française des Sociétés Sciences naturelles: Office central de Faunistiqu Pp. 70. (Paris: Paul Lechevalier, 1923.) 8 franc

PROF. BOUVIER points out in his introduction that th pycnogonids of the French fauna have never be studied in systematic fashion. There are memoirs b Hoek on the species found at Roscoff, by Grube on tho of S. Malo, and a recent account by Cuénot of h observations on pycnogonids at Arcachon. The auth has turned to G. O. Sars' well-known monograph an to that of Dohrn for further information, and from the and from Hoek's work he has borrowed most of th figures used in the present volume. He gives an accou of the external morphology, the internal anatomy, an the development and biology, and in a brief discussi of the affinities states his view that the pycnogonids a arachnids. In a short reference to the forms with fi pairs of legs, *e.g.* Decalopoda, he concludes that the are primitive relatively to Colossendeis. Keys are giv for the orders, families, genera, and species, and wi the help of these and the clear illustrations the dete mination of any given specimen is fairly easy. Th concise memoir will be very useful to collectors on t shores of Great Britain who have an interest in th group.

Letters to the Editor.

The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*]

The Mass Spectra of Zirconium and some other Elements.

AFTER repeated failures I have now succeeded in observing the mass rays of zirconium. Their detection is only possible under very favourable conditions with the most sensitive schumannised plates. Zirconium gives mass lines 90, 92, 94 and a doubtful one at (96), with relative intensities, very roughly, 10, 2, 4, (1) respectively. The masses of the first three can be determined with unusually high accuracy, owing to the incidental presence among them of a faint doublet 93, 95 due to CBr. There is no appearance of asymmetry in the spacing, so that the masses of the isotopes of zirconium must be very closely integral with those of bromine; that is to say, less than whole numbers by about one-tenth of a unit. The atomic weight may therefore be roughly estimated as 91·4 or 91·2, according to whether the mass number 96 is included as an isotope or not.

Successful mass spectra have been obtained with cerium (at. wt. 140·25), which indicate that it consists of a strong component 140 and a weak companion 142. Further experiments with neodymium (at. wt. 144·27) establish its principal isotopes as 142, 144, 146, with a possible (145).

Continuous work with anode mixtures not containing iodide has reduced the intensity of the iodine line sufficiently to warrant a further search for light isotopes of barium. Its principal line 138 has been obtained of great intensity, but there is no trace whatever of any mass number less than 136. There is some evidence of a faint component at 136, and, since the great intensity of the 138 line makes resolution impossible, 137 may also be present. It seems quite certain, however, that, even if both exist, they can only do so in quantity quite inadequate to account for the low value of the atomic weight (137·37) at present in use.

Incidentally, during this work I have obtained mass spectra of silicon under conditions affording satisfactory confirmation of the presence of Si^{30}, previously in some doubt. Its line is a little less intense than that of Si^{29}, in excellent agreement with Mulliken's observations on band spectra (NATURE, March 22 and April 5, pp. 423, 489).

It will be noticed that the above results are on the whole in fair agreement with the predictions made by A. S. Russell. F. W. ASTON.

Cavendish Laboratory, Cambridge,
August 8.

The Zeeman Effect in Strong Magnetic Fields.

IN a recent paper (Proc. Roy. Soc. A, vol. 105, p. 691, 1924), one of us has given an account of a method for the production of intense magnetic fields, with the limitation, however, that the field only lasts for a time of the order of 1/100th sec. We are now investigating the Zeeman effect in these intense fields. These fields allow the use of a quartz spectrograph in place of the usual large concave grating or interferometer, etc.

For the source of light, we have been using a spark produced in a special way from a large high tension condenser battery, and the intensity is sufficient for one spark to produce a spectrum photograph, while most of the emission lines remain quite sharp. The spark takes place in a coil of 5 mm. internal diameter in which the field is produced, and the spark and the current in the coil are timed to occur together.

We have so far investigated mainly the "longitudinal" Zeeman effect (observation in the direction of the lines of force) in fields of about 130,000 gauss as being technically easier than the "transverse" effect. The accompanying photograph (Fig. 1), enlarged from the original six times, shows one of the results. The lines are the first members of the principal series of doublets of ionised calcium (Ca II) and of the sharp series of doublets of aluminium. It is feared, however, that the latter may not show clearly in the reproduction, though they are quite obvious in the original. The magnetic separation is about 3 Å.U.

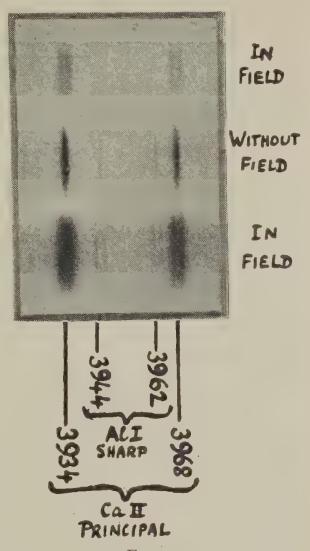

FIG. 1.

Generally speaking, the results so far obtained on lines of various elements indicate that the magnetic splitting is, except for the larger scale, identical with that obtained in ordinary cases. We have, however, observed some interesting cases of the Paschen-Back effect, partial and complete. We may mention in particular the case of the Be group 2650, given by Paschen-Götze as the *p*, *p'* group of Be, and as consisting of six extremely close lines. We have found that this group taken as a whole shows the normal Zeeman effect.

We have observed some interesting cases of lines appearing strongly in the spectrum taken in the field which do not appear in the comparison spectrum, and other cases of lines disappearing in the field. A further effect observed is that the lines produced in the field are shifted towards the red by varying amounts. It is possible that this is a kind of pressure effect, due to the production of the spark in the field, and to investigate the matter further, and for other reasons, we hope shortly to deal with absorption spectra. We have also a project for the production of still higher fields (probably up to 250,000 gauss) by cooling the coil with liquid air in order to be able to use more turns in a coil of given resistance.

Biology and Sociology.

I SHOULD like to direct attention to a point connected with the above topic which Dr. Malinowski does not mention in his article in NATURE, July 19.

What is of importance is not the transference of ready-made biological theories to the field of sociology, but rather that the problems of cultural evolution should be approached from the same detached and objective point of view as that of the biologist. Natural selection, for example, can be strictly said to operate

in the latter case only where competition may result in the extinction rather than the modification of whole groups, where, alone, a particular cultural element has a definite survival value in the biological sense. But it is none the less true that the process of what may be termed "bio-economic adjustment" is still everywhere proceeding, and the character of the culture-milieu of a particular society at any moment must be regarded, in the main, as a reflex of the whole complex of primary and secondary environmental factors which operate upon the group-members, in addition, usually, to a number of functionless or residual characters of historical interest, which were evolved in relation to anterior conditions.

Perhaps the most important lesson that sociology can learn from biology is the fundamental distinction between the purely *historical* problem in evolution and the question of the *machinery of variation*, a distinction which, in sociology, is unfortunately often disregarded. We desire to know, not only what has happened, but also how it happened, and why it happened only in this particular time and circumstance. It is too often tacitly assumed, especially by the "new" anthropologists, that to point out a possible derivative origin of a certain cultural element is a sufficient explanation of its existence in a particular society. The conditions which govern *assimilation* are of equal if not greater importance. To give a homely example: if Dr. Malinowski were to appear in his class-room wearing a Malayan kris, this would introduce a new cultural element into British academic life; but it is very doubtful if it would afford any research problem for the future historical sociologist.

Moreover, just as in biology the problem of variation is being most usefully attacked by concentrating upon small definite changes in organic characters, which are actually taking place now under observational conditions, rather than upon the historical background of evolution: so we must hope to make most progress in the study of cultural variation by observing and correlating small specific changes in contemporary civilisation, rather than the character of past or primitive societies. It is more useful to analyse carefully the conditions which are associated with the incidence of prohibition or divorce reform than to speculate about the origin of totemism.

To contrast the instinctive and physiological dispositions of an insect colony with the "culture" of human society does not take us very far, unless we have a clear understanding of the factors upon which cultural changes depend. This latter question cannot be discussed here, but it may be pointed out that whereas the *limiting conditions* of social changes are bio-economic, the machinery of variation is psychological. The psychological factors involved are partly rational, but mainly in the nature of specific emotional dispositions in relation to particular social facts. Dr. Malinowski's suggestion that these definite but variable ethical and æsthetic attitudes are due to the secondary modification of primary instincts does not help very much. To say, for example, that humanitarian sentiment is a secondary derivative of the parental instinct does not explain why the *average* emotional reaction of successive generations of the same society towards specific questions (*e.g.* slavery, criminal punishment) should often be so markedly different. From the point of view of cultural evolution, it is the exact character, sequence, and correlations of these specific reactions which is of principal importance.

C. W. SOAL.

Scratton Lodge, Prittlewell, Essex.

IN the article referred to by Mr. Soal, I have tried, on a parallel between an insect aggregate and human society, to trace the breach of continuity between biology and the science of human culture, as w as to establish their points of contact. I have al criticised certain illegitimate attempts at transferen of methods and concepts from the study of livi organisms to that of culture and social organisatio notably the society-organism simile, the theory "herd instinct," and certain crude applications Darwinism in sociology. In the above letter it suggested, obviously in criticism of the last-mentione contention of mine, that I have neglected to discu the applicability of natural selection to the study human culture.

It is now a commonplace for any competer sociologist that natural selection, as we know it fro biology, cannot in any way operate on human i individuals within the community—and this is mac clear to any one who reads my above-mentione article. Nor can the principle be applied to an struggle or competition of groups within society. (F searching criticism, see J. Novicow, "La Critique d Darwinisme sociale," Paris, 1910, and III. Abteilun "Die allgemeine biologische Soziologie," in P. Barth "Die Philosophie der Geschichte als Soziologie," p 260-437, 4th ed., 1922.)

But there remains the question: Can natur selection or Darwinism in general be applied t varieties of the human species, to races, or to enti populations, or to types of human culture taken as whole? Here also there is no new ground to breal for the "struggle of races" (Rassenkampf) has bee used, abused, and rejected as a leading principle social science, while laws of growth, culmination, an decay of nations and cultures have been constructe and demolished more than once. Again, what coul be called "the struggle of cultures," the contac mixture, and transmission of whole types of civilisa tion or elements thereof, is really the fundamenta principle of the "new anthropology" mentioned b the above correspondent. How far the adherents c this school will succeed in explaining everything b this principle, or in constructing a new theory c universal advance by contact of cultures, remains t be seen. At present they are clearing the ground amassing material, and working out particular ques tions.

Thus the problem which Mr. Soal recommends *e passant* to the attention of anthropologists is, as matter of fact, the fundamental problem of the scienc of man, inspiring all the general theories and enterin into all detailed work on concrete subjects. It is of course, recognised to be so by all anthropologist who reflect on the aims of their science. So tha generalities such as that "natural selection . . . ca be strictly said to operate . . . where competitio may result in the extinction rather than th modification of whole groups"; and again, abou "bio-economic adjustment" or about "a reflex o the whole complex of primary and secondary en vironmental factors which operate on all the grou members," etc., will be of little use even to those who can grasp their somewhat cryptic meaning.

I think it is obvious that in this connexion biology cannot help us very much, for natural selection, as we see it at work in the world of plants and animals, cannot be applied to the study of societies. Natural selection operates on individual organisms, directly at grips with their environment, competing with other creatures who need the same food, every individual struggling by its own efforts, pursuing its own ends, and having to rely on its own anatomical and physiological endowment. A human society is not an individual organism; it possesses no anatomical or physiological equipment, it has no biological aim or needs of its own. It exists only by its own members and for their benefit. The type, the aim, and the

lue of its organisation and culture must be gauged
the manner in which it ministers to the wants of
e individuals which constitute it. Here then are
oblems so absolutely foreign to the biological theory
natural selection as to preclude any borrowing by
ciology from biology.

Mr. Soal's kind exhortation to anthropology that
should become "detached and objective," and that
should give up troubling about the "character of
ist or primitive societies," and study "prohibi-
on or divorce reform" instead, will no doubt be
mbly and hopefully received by other anthropolo-
sts as it is by the present writer; though I fear
at my experience in discussions about problems
uching liquor and sex seems to show that they do
t lead to an "objective or detached" frame of mind.
the attempt to follow his advice, we might realise
r. Soal's "homely example" of an anthropologist
ppearing "in his class-room wearing a Malayan
is," a tendency of which he seems to suspect me.
do not think there is any hope, either, that the
ience of primitive man should give up studying
imitive man, any more than that astronomers should
ve up studying stars, when advised to turn their
tention to turnips and potatoes, since this "is more
eful."

Solubility of Phosphates in Relation to Hydrogen Ion Concentration.

WITHIN the last few years statements have appeared
various journals giving the P_H values at which
rtain salts yield precipitates upon being rendered
ss acid. Some of these also record the lower limit
acidity at which precipitation is said to be com-
lete. It accordingly appeared to be of interest to
etermine the form of the solubility curve. This
as done for certain phosphates, using samples
rchased as pure and washed with distilled water
peatedly to remove traces of more soluble phos-
hates, etc. The determinations were made at air
mperature, about 10-12° C., upon solutions cleared
y the centrifuge, using the cœruleo-molybdate
action of Denigès. Nine determinations were
ade upon a sample of tricalcic phosphate (B.P.),
etween P_H7·0 and P_H5·1, hydrochloric acid being
ed to increase the acidity.

Over this range the solubility increased from 114
786 parts per million. When P_H values are taken
ordinates (the higher values being at the bottom of
e paper) and concentrations as abscissæ, the nine
ints give a curve which at first ascends steeply and
en becomes more nearly parallel to the concentra-
on axis; thus a small change in the P_H value is
companied by a large change in solubility. Accord-
gly the precise P_H value at which a precipitate is
rst obtained depends on the concentration of the
hosphate and precipitation is never absolutely com-
lete with the pure salt, even at P_H7·0. The phos-
hates of strontium and of barium give curves which
e qualitatively similar. The phosphate of mag-
esium is more soluble 450 p.p.m. at P_H7·7, and the
rve rises somewhat less sharply at the start; it
aches the value 1233 p.p.m. at P_H5·8.

$CaHPO_4$ is much more soluble than $Ca_3(PO_4)_2$, and
e solubility of the latter is increased if it contain
ny of the former as an impurity. $CaH_4(PO_4)_2$ was
und to dissolve readily, a slight deposit only being
ft; this does not appear to be the original salt.
he reaction given by the sample used was markedly
id, P_H3·6.

The phosphates of lead and zinc were found to be highly insoluble, lead only giving phosphate equivalent to 0·97 p.p.m. of P_2O_5 at P_H6·75 and zinc 1·11 at P_H6·85, nickel follows with 11·9 at P_H8·9. The readily hydrolysed ferrous and ferric phosphates appear to have solubility minima in the acid region, and the addition of alkali to bring the solutions to neutrality results in more phosphate becoming available in solution. These relations, being of importance in studies on plant nutrition, are being worked out, and it is hoped that the results may be published in more complete form within a year.

The Phosphide Eutectic in Cast Iron.

THE accompanying photomicrograph (Fig. 1) shows the phosphide eutectic in a grey cast iron at 5000 diameters. This shows that the constituent which appears as dark markings at ×1000, and is still commonly described as iron carbide, is actually duplex, and in fact very similar to pearlite, consisting of alternate laminæ of iron carbide and iron.

FIG. 1.—Phosphide eutectic in cast iron. ×5000.

It is recognised from the research of Stead that there would be present the three constituents of the triple eutectic, namely, iron phosphide, iron carbide, and austenite, or their transition products. Thus the presence of laminated pearlite, from the transformation of austenite, is accounted for. The pearlite thus associated structurally within the phosphide masses may conceivably be richer (it probably is, but may even be poorer) in carbon content than obtains in the normal pearlite ratio, Fe_3C 21Fe. Prof. Desch,

to whom I have shown several similar photographs, confirms the foregoing explanation. The photograph was taken at 5000 diameters by means of the super-microscope. F. ROGERS.

"Bitumen" in Meteorites.

THE statement that is currently repeated as to the existence of bitumen in meteorites does not bear examination. It is based on a number of investigations that were made between 1834 and 1885 on the alcohol- and ether-soluble material obtained by extracting meteoric matter, but no recent work appears to have been done to throw further light on the subject. The weights of the samples examined were so small that quantitative analyses are not very convincing, but an undoubted uniformity of results can be traced.

There has been obtained a hydrocarbon (possibly containing sulphur and oxygen), melting about 114° or 120° C., accompanied by free sulphur and graphite —and this is the material, present in an extra-terrestrial body, that is quoted to-day as evidence for the inorganic origin of terrestrial petroleum.

The suggestion now made is, that the presence of the hydrocarbon is due to the action of water on carbide after the arrival of the meteorite on the earth. The evidence for this is the following :

1. Iron-nickel carbide is found in meteorites.

2. Water poured on to powdered meteorite causes the production of "an alliaceous odour."

3. Phosphide is also present.

4. The water that is usually found in meteorites is considered by authorities not to be original, but to have been taken up at some subsequent time.

5. Soluble carbon compounds have been stated to be completely removed by solvents without preliminary pulverisation of the meteorite sample; that is, they exist in cracks and pores which are just the positions into which water could percolate.

6. Solid hydrocarbons are formed by the action of water on carbides of metals of high valency. These carbides are actually present though in small quantities and not often ; these hydrocarbons are also present in small quantities and not often.

This explanation, if correct, dissipates the present contradictory evidence of the presence of, on one hand :

(*a*) graphite, suggesting crystallisation from an iron magma ;

(*b*) carbide and phosphide, suggesting high temperatures of formation ;

(*c*) an outer skin, indicating the attainment of a high temperature on reaching the earth's atmosphere ; and, on the other hand,

(*d*) of a hydrocarbon of low melting point, absolutely precluding the possibility of a high temperature after its formation. PERCY EDWIN SPIELMANN.

Comparison of Wave-lengths with a Fabry and Perot Étalon.

IN the issue of NATURE for June 28, p. 926, Prof. Robertson, discussing the "Comparison of Wave-lengths with a Fabry and Perot Étalon," points out that for determining fractional orders of interference it is sufficient to measure only the linear diameters of the interference rings. This practice has been used extensively at Mount Wilson Observatory for ten years. It was described in Mount Wilson Contributions, No. 137, *Astrophysical Journal*, 46, 138, 1917, and No. 202, *Astrophysical Journal*, 53, 42, 1921, where full details will be found. It was shown that the method offers marked advantages, such as (reduction of labour, (2) smaller probable erro (3) convenient numerical checks which diminish t chances of mistakes in computation.

It is unfortunate that, on account of the form which Prof. Robertson expresses the idea of t method, he has committed, inadvertently no doub the error of deriving six values of the fractional ord from only four observations, and in consequence he fin an incorrect result with too small a probable error.

It seems to me preferable to write the fundament equation in the form

$$\alpha = 1 - n + cd_n^2$$

where α is the fractional order, n is the number of t ring of diameter d_n, counting the innermost as t first, and c is a constant for all the rings of a giv line, depending on the integral order of interferenc the focal length of the projector, and the magnific tion in the spectrograph. It is evident that the tv unknown quantities α and c may be evaluated if least two diameters are measured, and that if diameters are measured only $q - 1$ independent valu of α may be found.

In the practical use of the method for extende investigations, the constant c is derived from combination of the measurements on many lines, a it becomes legitimate to obtain q independent valu of α from q diameters measured on a given line.

A Substitute for the McLeod Gauge.

THE results of our experiments do not confir Mr. Fleuss's statements (NATURE, July 5, p. 1 Even if the water vapour is always at a pressure le than its equilibrium vapour pressure at room temper ture, the McLeod gauge reads low and usually i consistently. The reason is, of course, to be fou in the absorption of water by glass. Water vapo will condense on glass when its pressure is raise even when the final pressure is no greater th 0·001 mm. ; the amount that condenses increas with the time, so that the reading of the gau depends on the rate at which the mercury is raise All this is quite familiar to those who work wi modern high vacuum apparatus ; but Mr. Fleuss statements, if unchallenged, might mislead so who are only beginning to acquire their experience.

A Hundred Years of Electrical Engineering.[1]

By Prof. G. W. O. Howe.

If any one event can be regarded as the birth of electrical engineering, it is surely the discovery by Faraday in 1821 of the principle of the electro-motor; that is, that a conductor carrying a current in a magnetic field experiences a force tending to move it. It is noteworthy that ten years elapsed before Faraday discovered, in 1831, the magneto-electric induction; that is, the principle of the dynamo. Four years later, Sturgeon added the commutator or "uniodirective discharger," as he called it, and in 1845 Cooke and Wheatstone used electromagnets, which Sturgeon had discovered in 1825, instead of permanent magnets. It was during the years 1865–1873 that the shunt and series self-excited dynamo, using a ring or drum armature and a commutator of many segments, finally evolved.

The early workers in the field do not appear to have realised the intimate connexion between the dynamo and the motor, for, although the principle was discovered by Lenz in 1838, it only appears to have become generally known about 1850 that the same machine could be used for either purpose. The principle underlying the whole modern development of electrical engineering, namely, the generation of electrical power by a dynamo, its transmission to a distant point, and its retransformation to mechanical power by an electric motor, appears to have evolved about 1873.

The development of the dynamo during the 'seventies and the simultaneous development of the incandescent lamp led to the general introduction of electric light during the 'eighties. Attempts to make incandescent electric lamps had been made so early as 1841, when de Moleyns patented one having a spiral platinum filament; and in 1847 Grove illuminated the lecture theatre of the Royal Institution with such lamps, the source of power being primary batteries; but it was not until 1878 that the commercial development of the incandescent electric lamp was begun by Edison and Swan.

One of the earliest complete house-lighting installations was put in by Kelvin in 1881. A Clerk gas-engine was used to drive a Siemens dynamo, a battery of Faure cells was fitted up, and every gas-light in his house and laboratory at Glasgow University was replaced by 16 candle-power Swan lamps for 85 volts. He had to design his own switches and fuses, etc., for such things were almost unknown.

For about twenty years the carbon-filament lamp held the field without a rival for interior illumination, and, although attempts were made to improve its efficiency by coating the filament with silicon, the plain carbon filament only gave way finally to the metal-filament lamp. One of the most interesting developments in the history of electric lighting was the Nernst lamp, which was introduced in 1897; the filament consisted of a mixture of zirconia and yttria, and not only had to be heated before it became conducting but also had to be connected in series with a ballast resistance in order that it might burn stably. The way in which these difficulties were surmounted and the lamp, complete with heater, ballast resistance, and automatic cut-out, put on the market in a compact form occupying little more space than the carbon-filament lamp was, in my opinion, a triumph of applied science and industrial research. The efficiency was about double that of the carbon lamp. About this time, however, a return was made to the long-neglected metal filament. The osmium lamp invented by Welsbach in 1898 was put on the market in 1902, to be followed two years later by the tantalum and tungsten lamps. The latter was greatly improved by the discovery in 1909 of the method of producing ductile tungsten and by the subsequent development of gas-filled lamps in which the filament can be run without undue volatilisation at such a temperature that the consumption is reduced in the larger sizes to 0·6 watt per mean spherical candle-power. This improvement of eight times as compared with the efficiency of the carbon-filament lamp has led to the gradual replacement of the arc lamp even for outdoor illumination. The arc lamp was introduced at about the same time as the carbon-filament lamp, the Avenue de l'Opéra having been lit with Jablochkoff candles in 1878. The open arc was developed during the 'eighties; the enclosed arc, giving long burning hours and thus reducing the cost of recarboning, was introduced in 1893, and the flame arc in 1899. During the first few years of this century the flame arc was brought to a high stage of development and the consumption brought down to about 0·25 watt per candle-power, but the necessity of frequent cleaning to prevent the reduction of efficiency by dirt, and the labour of recarboning, have led to its abandonment in favour of the less efficient filament lamp.

Before leaving the subject of electric lighting I would point out that it is remarkable that the first great application of electric power should have been for the production of electric light, since it is probably the least efficient of all its applications. The overall efficiency of a small power station supplying a lighting load and having therefore a very poor load factor would not be greater than about 6 per cent. from coal to switchboard, the steam-engine being, of course, the principal offender. Of the total power supplied to and radiated from a carbon-filament lamp not more than about 2 per cent. was radiated as light, so that the overall efficiency from coal to light was 2 per cent. of 6 per cent., which means that of every ton of coal burned at the power station with the object of producing light all but about 3 lb. was lost as heat at various stages of the transformation. Even now, with up-to-date steam plant and gas-filled lamps, the overall efficiency from coal to light is not equivalent to more than 40 to 60 lb. of coal out of each ton. The electrical engineer may derive a little comfort from the knowledge that the purely electrical links are the most efficient in the chain.

Whilst on the subject of efficiency I might point out that the difference between the prices at which coal and electrical energy can be purchased by the ordinary citizen corresponds to the losses incurred in the power station; that is to say that the cost of the generation and distribution of the electrical energy is covered by

[1] From the presidential address to Section G (Engineering) of the British Association, Toronto, August 7.

the better terms on which the power station can obtain fuel. In Glasgow the writer pays 5*l.* per ton for anthracite to burn in a slow-combustion stove; taking the calorific value of anthracite at 9000 kilowatt-hours per ton, which is equivalent to 14,000 British thermal units per lb., this works out at 7½ kilowatt-hours for a penny. For electrical energy for heating and cooking purposes the writer pays a penny per kilowatt-hour. This ratio of 1 to 7½ will correspond fairly closely to the overall efficiency of the power station. In view of the high efficiency and convenience of slow-combustion stoves, it is evident that electric heating cannot be expected to compete with them for continuous operation; for intermittent heating the question is very different.

Returning from this digression to the development of the direct-current dynamo, it may be noted that the drum armature now almost exclusively employed was invented in 1872 by von Hefner Alteneck, and gradually displaced the ring armature of Pacinotti and Gramme. Although Pacinotti's original ring armature was slotted, smooth armatures were preferred for many years, until the mechanical superiority of the slotted armature caused the disappearance of the smooth core with its wooden driving pegs which were employed to transmit the turning moment from the conductors to the core. The commutator and brushes were a great source of trouble, but by the gradual elimination of unsuitable material and by better design and methods of manufacture the commutator has been made a most trustworthy piece of apparatus. The difficulties of commutation, and especially the need of continual adjustment of the brush position, were largely overcome by the invention of the carbon brush by Prof. George Forbes in 1885. It should be pointed out that the commutating poles, which have come into use so much in recent years, were originally suggested in 1884, and are therefore older than the carbon brush.

The realisation of the idea of supplying electric current from a power station for lighting houses in the neighbourhood owed much to the energy and business ability of Mr. Edison. He exhibited his first "Jumbo" steam-driven dynamo in 1881, and installed two sets at Holborn Viaduct in the following year to supply current to neighbouring premises. The output of these sets was about 90 kilowatts at 110 volts, which was so much larger than anything previously constructed that the name "Jumbo" was applied to these sets. About 1890 the multipolar type began to replace the bipolar type for the larger sizes. The size of the single units employed in power stations gradually increased with the increasing demand, and by 1895, dynamos of 1500 kilowatts had been installed.

Ferranti was apparently the first to suggest that the power station should be outside the city, at a point convenient for fuel and water supply, and that the power should be transmitted into the city by high-voltage alternating currents. In 1890 he built the Deptford Station for the London Electric Supply Company, and installed 1000-kilowatt 10,000-volt alternators. This was the pioneer high-voltage underground cable transmission, and much was learnt concerning the peculiarities of alternating currents when transmitted over cables of considerable capacity. The following year, 1891, saw the first long-distance transmission by means of overhead conductors in connexion with the electrical exhibition at Frankfort-on-Main three-phase power was transmitted, at 8500 volts, from a water-power station at Lauffen to Frankfort, a distance of 110 miles.

This development of the use of high-voltage alternating currents followed the development of the transformer. Gaulard and Gibbs patented a system of distribution involving transformers in 1882, and although their patent was upset in 1888 on the ground of its impracticability, the present method of using transformers for the distribution of electrical power was introduced in 1885, and shown at the Inventions Exhibition in London in that year. Although from 1890 onwards there has been a steady increase in the size of alternators and transformers and in the voltage employed for long-distance transmission, the last few years have seen a really amazing increase in the size of the units employed. In 1913 the largest 2-pole turbo-alternators had an output of 3000 revs. per minute of about 7500 kilowatts; such machines are now made up to 30,000 kilowatts, and 4-pole alternators are running at 1500 revolutions per minute, with an output of 60,000 kilowatts. This increase in size and in peripheral speed has been made possible by improvements, both in the material and in the design. With a bursting speed 25 per cent. above the running speed the peripheral speed can now be raised to 150 metres per second. Improved methods of cooling and a better understanding of the various causes of loss in the armature have enabled the materials to be used at higher current and flux densities.

This great increase in the size of units is not confined to the steam turbo-generator, as can be seen from the water-turbine sets recently added to the Niagara installation. Whereas the original Niagara turbines were of about 5000 horse-power, the new ones have an output of 70,000 horse-power at the low speed of 107 revolutions per minute.

The importance of cheap electric power has led to this great increase in the size of the units in the generating stations. Any slight difference of efficiency between a 10,000-kw. and a 60,000-kw. alternator is of little importance, and would certainly not counterbalance the decreased factor of safety due to concentrating the whole power supply in three or four large units, instead of distributing it between a dozen or more units. The reason for the adoption of the smaller number of large units lies almost entirely in the decreased capital cost per kilowatt of plant. In my opinion, however, there are many cases in which too much consideration has been given to this factor, and too little to the importance of a guaranteed continuity of supply.

Until recently, the only means of producing a large amount of high-voltage D.C. power was by connecting a large number of carefully insulated dynamos in series as in the well-known Thury system of power transmission. Within the last two or three years another method has been developed, viz., the so-called transverter, which consists of an arrangement of transformers and a system of rotating brushes, whereby a three-phase A.C. supply is converted into an almost steady continuous current. The first apparatus of this type to be exhibited is installed at the British Empire Exhibition at Wembley, and is designed to deliver

ontinuous current at 100,000 volts. It can also be sed for the reverse process. It would thus enable a hree-phase generating station and a three-phase sub-tation to be connected by a direct-current transmission ine, thus avoiding not only the maximum voltage of ·4 times the effective voltage, which was one of Lord Kelvin's objections to the A.C. system, but also all rouble due to the capacity and inductance of the line.

Electric traction represents one of the most important ranches of electrical engineering. It shares with the etrol motor the distinction of having absolutely re-olutionised the methods of transport within a single eneration. In its origins it is nearly a century old, or attempts were made in the 'thirties to apply araday's newly discovered principle to the propulsion f vehicles, but, with very primitive motors and primary atteries, these attempts were doomed to failure. The levelopment of the dynamo and motor in the 'seventies pened the way to further experiments, and at the Berlin Exhibition in 1879 a line one-third of a mile ng was shown in operation, a locomotive drawing hree cars. The first regular line was opened to traffic ear Berlin in 1881; it worked at 100 volts and the urrent was collected from an insulated rail. Toronto vas the scene of one of the earliest experiments in America; C. J. van Depoele, after some experiments t Chicago in 1882 and 1883, ran an electric locomotive n 1884 between the street-car system and the Exhibi-ion in Toronto.

The difficulties were enormous. The carbon brush vas not invented until 1885, and commutation in a eversible motor with copper brushes caused great rouble; armature construction and winding was in ts infancy; the suspension of the motor and the nethod of gearing it to the car axles were problems vhich were solved only after much experience. Rapid progress was made after about 1887, and the closing ears of the century saw an enormous development, he elimination of horse tram-cars throughout the world and the electrification of a number of city and suburban railways.

Of the various systems of collecting the current, only two have survived for street-cars, namely, the usual over-head wire and the exceptional underground conduit; in the case of railways there is no necessity for a conduit, and the conductor rail is carried on insulators above the ground-level.

Although 500-volt D.C. supply has been standardised for street tramways, the relative merits of D.C. and A.C. for electric railways has been a burning topic for more than twenty years, and is now perhaps more burning than ever. It is somewhat akin to the battle of the gauges in the early days of steam railways, for it involves in many cases the problem of through-running, if not now, in the not very distant future. Although the three-phase system was successfully installed in Northern Italy, it has grave disadvantages, and the battle now is confined between direct current at an increased voltage of, say, 1500 to 2000 volts, and single-phase alternating current. In the latter case there is, moreover, a further question as to the best frequency to adopt, this being usually either 25 or $16\frac{2}{3}$. The development of the A.C. commutator motor to the stage where it was applicable to traction took place during the first few years of this century, and, although in itself it is inferior to the D.C. motor, it introduces so many simplifications and economies in the transmission of the power from the generating station to the train that experts are very divided as to the relative merits of the two systems for main-line electrification.

I can only refer briefly to the applications of electrical power to chemical and metallurgical processes. Some of these are purely electro-chemical, others are purely thermal, while in many processes the electric current performs the double function of melting and electrolysing. The possibility of electroplating was discovered so early as 1805, but the commercial application of electro-chemistry on a large scale was impossible before the development of the dynamo. Within the last thirty years the provision of an abundant supply of electrical power has led to the creation of enormous electro-chemical industries; I need only instance the production of aluminium, carborundum, and calcium carbide. These industries have usually been established near a hydro-electric plant and provide a load of very high load-factor.

I turn now to what may be called both the earliest and the latest application of electricity; that is, its use for transmitting intelligence. One of the greatest factors in the development of our modern life has undoubtedly been the network of wires and cables which has spread over the whole earth, making possible an almost instantaneous transmission of intelligence and interchange of opinions. In the early days of electrical science the discovery of a new property of electricity was followed by attempts to utilise it for this purpose. So early as 1746 there are records of the use of frictional electricity for the purpose, and distances up to four miles were tried. In 1774 Lesage of Geneva proposed 26 wires in earthenware pipes with pairs of pith-balls at the end of each wire, which flew apart when the conductor of a frictional machine was brought near the other end of the wire. A current of electricity was unknown until Galvani's discovery in 1789, and Volta's pile was first constructed in 1792. Carlisle in 1800 found that water was decomposed by passing the current from a Volta pile through it, and this was the basis of the telegraph proposed by Sömmering in 1809, in which 26 wires ended in 26 metallic points arranged in a row along the bottom of a kind of aquarium. By means of a lettered keyboard at the sending end the current could be applied to any wire, and a stream of bubbles caused to rise from the appropriate point, each point being duly labelled with its appropriate letter. The magnetic effect of the electric current was discovered in 1819, and immediately replaced the previous methods in efforts to develop an electric telegraph; except for the attempts to make a high-speed chemical telegraph, all subsequent telegraph systems have employed the magnetic effect of the current. A great many of the fundamental inventions of telegraphy were made in the 'thirties; the list includes the needle instrument of Cooke and Wheatstone, the sounder of Henry, the dot-and-dash inker of Morse, and the use of the earth as a return by Steinheil. Although the needle instrument is now obsolete, the sounder and Morse inker are still commonly employed. Many have been the devices for increasing the amount of traffic which can be worked over a single line, either by the simultaneous use of the line by a number of

operators, as in the quadruplex and multiplex systems, or by punching the messages on paper tapes, which can then be fed into an automatic transmitter working at a speed ten to twenty times that attainable by a manual operator. In the most up-to-date systems the perforation of the tape is done by the operators working an ordinary typewriter keyboard, and the received message is printed in ordinary type, a single wire carrying eight messages simultaneously, four in either direction, at a speed of 40 words per minute.

The need for telegraphic communication between countries separated by water was so much the greater because of the slowness of other means of communication, but the difficulties in laying and maintaining 2000 miles of insulated wire on the bottom of the sea must have appeared almost insuperable to the early workers; fortunately, however, there were men who had the necessary vision and courage. The flimsiness of the early cables suggests that the pioneers underestimated the magnitude of the problem which faced them, which was perhaps fortunate. A cable was laid between Dover and Calais in 1850; it lived only a single day, but it was replaced in the following year by a successful cable.

The first cable was laid across the Atlantic in 1858, and, although in the light of our present knowledge we know that it could not have had a very long life, its failure after a few weeks of preliminary communication was primarily due to misuse owing to the ignorance of those in charge. Although much costly experience had been gained in the laying of cables in various parts of the world since this first attempt to span the Atlantic, the success of the second Atlantic cable in 1866 was largely due to the scientific ability of Kelvin and to his untiring application to the project at every stage of the manufacture and laying of the cable.

Turning to another branch of electrical communication, it is no exaggeration to say that modern business life has been revolutionised by the telephone, which will shortly celebrate its jubilee, for it was in 1876 that Graham Bell invented the magnetic telephone receiver, although others, notably Reis, had been working at the problem since 1861. Bell showed his telephone in operation at the Philadelphia Centennial Exhibition in 1876, and Kelvin, who was one of the judges, brought one back with him and demonstrated it to Section A of the British Association, at its meeting in Glasgow in the autumn of 1876.

A successful telephone system requires much more than efficient transmitters and receivers, and the great development which has taken place has been largely a matter of improvement in the design of the many elements that go to make up a telephone exchange. The modern manual central-battery exchange, in which one has only to lift his receiver to call the operator and be connected in a few seconds to any one of 10,000 other subscribers, is a marvel of ingenuity and construction. But this is now gradually being replaced by the greater marvel of the automatic system, in which the operator is eliminated and the subscriber automatically makes his own connexion to the desired subscriber. Attention should be directed to two outstanding inventions in the actual transmission of telephony over long distances, namely, loading and repeaters. It was Oliver Heaviside who in 1885 proposed to improve the range by increasing the inductance of the line. Although this revolutionary suggestion fell on deaf ears for fifteen years, it ultimately proved to be one of the great inventions of telephony; it is of special importance in underground and submarine telephone cables, the electrostatic capacity of which otherwise seriously limits the range. The other outstanding novelty is the introduction of repeaters at intermediate points in long telephone lines. These repeaters are specialised types of low-frequency amplifiers; they were made commercially possible by the invention and perfection of the three-electrode thermionic valve. The attenuated speech currents arriving at the end of a section of line are amplified and thus given a new lease of life before being passed on to the new section. By using a large number of such repeating stations, telephonic communication has been established between New York and San Francisco.

Turning now to radio telegraphy and telephony, one cannot but marvel at the rapidity of its development and the inroad that it has made during the last two or three years on the domestic life of the whole civilised world. The theory of Clerk Maxwell in 1864 and the laboratory experiments of Hertz in 1888 found their first practical application in Marconi's Italian experiments in 1895 and his demonstrations in England during the following year. Much of the rapid progress was due to his perseverance, vision, and courage in perfecting apparatus for short-distance work, and simultaneously experimenting over long distances, and thus, in the year 1901, settling by actual demonstration across the Atlantic the vexed question as to whether the waves would pass around the earth over distances of several thousand kilometres or go off into space.

The accomplishment of long-distance communication bristled with difficulties, largely due to unsuspected atmospheric effects which are still little understood; but such progress has been made and is continually being made that one dare not now adopt an incredulous attitude to the wildest dreams or forecasts of what is to be accomplished by "wireless." The commonplace facts of to-day would have appeared beyond the bounds of possibility ten or twenty years ago.

By the aid of electricity the energy of the coal or of the lake or river a hundred or even two hundred miles away is transmitted noiselessly and invisibly to the city, to supply light and warmth, to cook the food, to drive the machinery, to operate the street-cars and railways. By its aid one can flash intelligence to the most distant part of the globe, hold conversations with friends hundreds or even thousands of miles away, or sit in one's home and listen to music and lectures broadcast for the entertainment or instruction of all who care to equip themselves with what may almost be regarded as a new sense. Whereas thirty years ago a ship at sea was completely isolated from the life and thought of the world, it is now in continuous communication with the land and with every other ship within a wide range. In no branch of electrical engineering, however, is there any suggestion of having reached finality; on the contrary, rapid development is taking place in every direction, and we can look forward with confidence to an ever-increasing application of electricity to the utilisation and distribution of the natural sources of energy for the benefit of mankind.

The Frequency of Birds over the High Atlantic Ocean.

By P. JESPERSEN, Copenhagen.

THE Danish Commission for the Study of the Sea has, during the years 1913 and 1920–1922, under the direction of Dr. Johs. Schmidt, made a series of marine-biological investigations in the northern part of the Atlantic Ocean and in West Indian waters. The following four expeditions have been carried out: in 1913 with the schooner *Margrethe*, in 1920 and 1921 with the motor-schooner *Dana*, and in 1921–1922 with the research steamer *Dana*. So far as circumstances permitted, ornithological observations were also made on these expeditions, and it is on the diary of these observations, in combination with notes made on various voyages to the United States of America and to the West Indies, that the present account is based. In this I shall endeavour to give, on general lines, an idea of the frequency of birds over the various parts of the Atlantic.

In what follows I deal only with observations made on the ocean, and as such I consider those made at places where the distance from land was at least 50 miles. We have in all, observations on the high seas on 462 days, covering an area from the Faroes (about 62° N. lat.) to about 5° N. lat. In the area between 10° and 50° N. lat. the observations cover the whole breadth of the Atlantic from the coasts of Europe and Africa right across to the coast of America, whereas north of 50° N. lat. observations were available only for the eastern part of the Atlantic. Of the total number of days of observation the greater part, namely 254 days (about 55 per cent.), were spent in the area between 20° and 40° N. lat. and 40°-70° W. long., thus chiefly in the Sargasso Sea. Observations were made at all times of the year, the majority (about 62 per cent.), however, having been made in the six summer months, and there are few observations for the winter months north of 40° N. lat.

It is well known that the frequency of birds differs greatly in the various parts of the Atlantic. In general, it may be said that the frequency decreases greatly with the distance from land, but there are also other circumstances which may have an influence in this respect.

In order to be able to form an opinion as to how far the frequency of birds varies for the different parts of the Atlantic, I have, on the basis of the daily observations mentioned, calculated the average number of birds observed *per diem* in the various areas. Of course these figures can by no means claim to be in any way accurate, in particular for areas where the number of birds is large, but they appear to be sufficient for giving an idea whether the frequency of birds is great or small in the various parts of the Atlantic. On the accompanying chart (Fig. 1) the average number of birds observed *per diem* within an area of 10 degrees longitude and 10 degrees latitude has been given. The figures in parenthesis give the number of days on which observations were made within the respective areas. As mentioned above, only observations have been included which were made on the high sea (at a distance from land of at least 50 miles), and only such birds have been considered which may be assumed as generally living over the high sea. Characteristic coast birds and all inland birds have been excluded from these calculations.

I have employed the following method in making my calculations: so far as possible, the number of all birds seen in the course of a day was noted down. In areas where birds appear in large flocks, the number could, of course, only be estimated, and the figures given for such areas, therefore, make no claim to great accuracy. I have in such instances placed a > before the number. When an average number is given for a certain area as, say, >13, this signifies that the average number of birds observed *per diem* within the respective area should be taken as, at the least, 13 birds. In many instances the actual number will probably be considerably higher. Birds which had followed the ship steadily for the whole day were counted once only, and the maximum number of birds seen together at one time during the day is, in such cases, given as the number of birds observed that day. Of course, there is always the possibility that the same individual bird is counted several times a day, and I have tried to avoid this so far as possible, but, particularly where individual birds of the same species are concerned, there will always remain the possibility of a repeated observation of one and the same individual. When a bird has been observed several times a day about the ship, I have considered it to be the same if at least six hours had not elapsed between the individual observations. Naturally fractions have resulted in these calculations, but all such fractions have been neglected. The average figure may therefore be understood thus: the number 1 means that the average

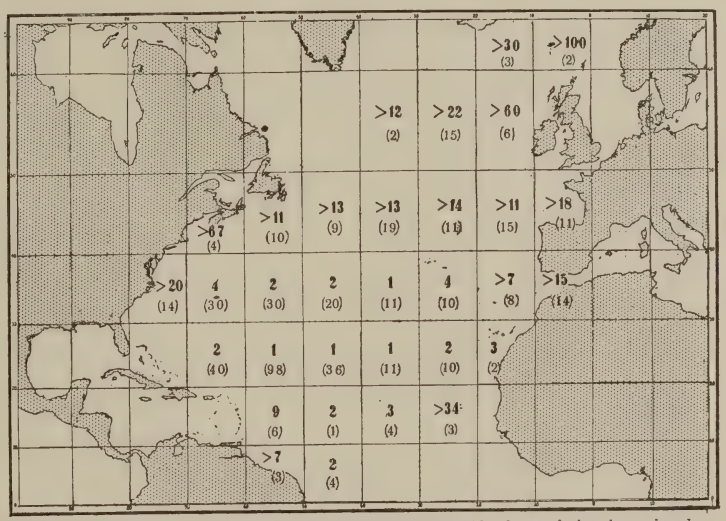

FIG. 1.—Average number of birds observed in 10° areas. The figures in brackets give the number of days on which observations were made in each area.

number of birds seen lies between 1 and 2, the number 2 that the average number lies between 2 and 3, and so on.

It is thus clearly seen in the accompanying chart that the frequency of birds is relatively larger the shorter the distance from land. Let us first consider the frequency of birds north of 40° N. lat. Here we have the largest number in the neighbourhood of the Faroes and to the west of Ireland. In the Bay of Biscay the frequency of birds is, however, considerably lower. The birds predominating in quantity here were fulmars, shearwaters, skuas, and kittiwakes.

Along the coast of America we have a high average figure south of Nova Scotia (>67). This is, in particular, caused by the large number of Wilson's petrels (*Oceanites oceanicus* Kuhl) which appears in the Gulf Stream area during the summer.

It will be observed that the frequency of birds decreases considerably with the distance from land north of 50° N. lat., but that we have quite considerable numbers over the middle of the ocean. The same applies to the area between 40° and 50° N. lat. Across the whole breadth of the Atlantic Ocean we, everywhere, meet birds in large numbers. It appears that the average figure is nowhere less than 11 birds a day. We are here chiefly in the Gulf Stream area, and the birds predominant are shearwaters, kittiwakes, skuas, and petrels.

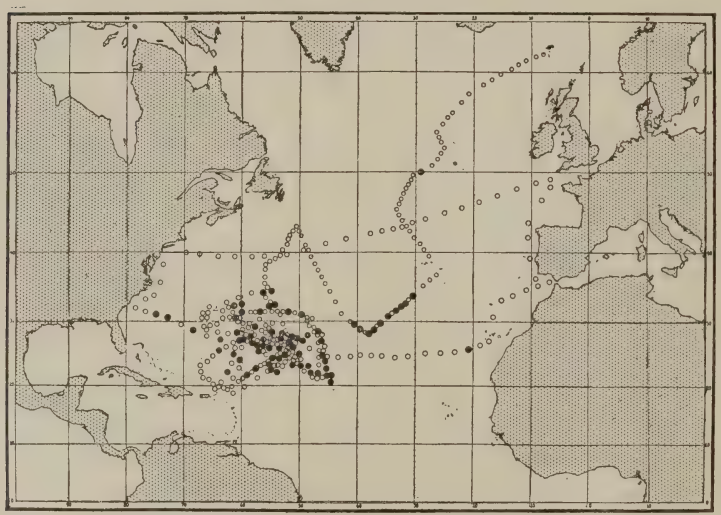

FIG. 2.—Routes of the *Margrethe*, 1913, and the *Dana*, 1920 and 1921. Black dots indicate positions in which no birds were observed during the day.

South of 40° N. lat. we notice that the frequency of birds decreases greatly. We have, particularly, ample data on bird life between 20° and 40° N. lat., and it will be seen that the number of birds is particularly small within those parts of the northern Atlantic which is generally termed the Sargasso Sea. Regarding the area between 30° and 70° W. long., it will be observed that, with the exception of the Bermuda area, the number of birds, on the average, does not exceed 1-2 *per diem*. The most characteristic bird for the Sargasso Sea is the tropic-bird (*Phaëthon americanus* Grant), but besides this bird we also observed in smaller numbers various petrels, shearwaters, and kittiwakes.

Between 30° and 40° N. lat. we have, however, a high frequency along the east coast of the United States and about Madeira, and in the Bay of Cadiz. Between 20° and 30° N. lat. the average numbers are particularly low across the whole ocean. South of 20° N. lat. we find a surprisingly high average figure about the Cape Verde Islands, owing to the sooty-tern (*Sterna fuscata* L.) appearing in flocks. The number of days on which observations were made here is, however, so small that no particular importance can be given to the individual figures.

The great difference between the number of birds on the high sea north and south of 40° N. lat. is thus striking. For still further illustrating this difference we shall, in what follows, consider another circumstance. During the various voyages it happened repeatedly that, on some days, not a single bird was seen from the ship, and it is of interest to have a look at the geographical position of such days of observation on which no birds whatever were seen. In the following chart (Fig. 2), showing the routes taken by the *Margrethe* in 1913 and by the *Dana* in 1920 and 1921, the days of observation are marked. The black dots indicate the positions in which no birds were seen during the day.

It thus clearly appears that almost all days of observation on which no birds were seen were south of 40° N. lat., being 1 day and 73 days respectively north and south of this latitude. The percentages are 1·3 and 28·1 respectively of all days of observation. This circumstance, furthermore, shows how small is the number of birds south of 40° N. lat. compared with the parts of the Atlantic north of this latitude.

The longest period during which the Danish expeditions did not see any bird was four days, and the longest period during which no birds were seen were all within the range of the Sargasso Sea, where the distance from land is considerable.

According to the available observations it appears that the number of birds within the range of the Gulf Stream is at least ten times as large as in the Sargasso Sea, and the question arises: what is the reason that birds are so scarce in the Sargasso Sea as compared with the area of the Gulf Stream? In large portions of the Sargasso Sea the distance from the nearest land is very great, and it is therefore possible that this fact is one of the reasons for the scarcity of birds, but this can scarcely be the real reason. In the central parts of the Atlantic, between 40° and 50° N. lat., where the distance from land is very considerable, the frequency of birds is, relatively, much larger than in any part of the Sargasso Sea.

The reason for the scarcity of birds in the Sargasso Sea is far more probably to be found in the small amount of food in this part of the ocean as compared to the Gulf Stream area. It seems reasonable to assume that the special fauna (fishes, crabs, etc.) belonging to the large quantity of drifting "Gulfweed" (Sargassum) must afford nourishment for more extensive bird life, but it is questionable whether this fauna plays any part as food for birds in the Sargasso Sea.

I have thus, in examining the contents of the stomachs of birds from the Sargasso Sea, never found the slightest trace of the characteristic fauna from the Sargassum, and it is therefore possible that it is difficult for the birds to catch the fishes and crabs hiding in these dense masses of drifting sea-weed. Examinations of the stomachs have, on the other hand, always shown that the birds, at least the majority of them, live on flying fishes and cephalopods. This shows that the birds in the Sargasso Sea do not avail themselves of the special Sargassum fauna but seek their food amongst fishes, cephalopods, etc., living free in the water.

It is therefore interesting to study the quantity of macroplankton to be found in the Sargasso Sea and the Gulf Stream respectively. In a previous paper [1] I have drawn a comparison between the quantity of macroplankton in various parts of the Atlantic, and it appears from this comparison that the quantity of macroplankton in the central parts of the Atlantic between 40° and 50° N. lat. is at least ten times as great as that in the Sargasso Sea.

The reason for the scarcity of bird life in the Sargasso Sea, as compared to that in the Gulf Stream area and, on the whole, in the northern Atlantic, may, therefore, safely be sought in the much smaller quantity of food to be found in the Sargasso Sea as compared to the parts of the Atlantic lying farther north.

[1] P. Jespersen: On the Quantity of Macroplankton in the Mediterranean and the Atlantic. Rep. on the Danish Oceanogr. Expeditions, 1908–10, vol. iii. 3. Copenhagen, 1923.

The Planet Mars.

By Dr. W. H. STEAVENSON.

THIS year's favourable opposition of Mars, which on August 22 is nearer to the earth than at any time between the eighteenth and twenty-first centuries, would seem a fitting occasion for a brief review of our present knowledge of the planet, together with an estimate of the prospects and probable direction of future research.

The object aimed at in physical observations of Mars may be considered as twofold. First, it is desired to determine, so far as available means will allow, the true appearance of the features presented to our view on the planet's surface; and, secondly, it is hoped, by careful and repeated observation of these features and the changes that occur in them, to reach some definite conclusions as to their real nature. Both of these objects have been kept in view from the earliest days of the telescope, but it is only in recent years that the second of them has begun to show reasonable prospect of fulfilment. The fact is, of course, that the one object is dependent on the other, so that the first must be attained, approximately at least, before the second can be pursued with any confidence of success. Thus it comes about that the history of Martian observation naturally divides itself into two stages, which we may term respectively that of cartography and that of interpretation. One, of course, is but a development of the other, and there is no sharp dividing line between the two.

From the earliest days of the telescope, it was recognised that the "spots on Mars" were relatively permanent features of the planet's surface, but the first attempts to construct even a rough map of them did not meet with much success. The drawings made by Sir William Herschel late in the eighteenth century are among the first on which we can recognise a number of markings that have since become familiar to us, and it was this great astronomer who, by his study of the polar caps, contributed the first piece of intelligent interpretation of Martian phenomena. But the first map of Mars, properly so called, was not produced until 1840, when Beer and Mädler gave to the world the results of their systematic work with a refractor of less than four inches aperture. This first map was followed, during the succeeding fifty years, by many others of increasing completeness and accuracy, each being in general the work of a single observer. During this period, thanks largely to the work of Schiaparelli, the areographical positions of the main features were fixed with some approach to finality, and a firm foundation was thus laid for future work. Finally, during the past thirty years or so, progress in cartography has been notably accelerated by the introduction of the co-operative system in observation, as exemplified by the work of such bodies as the British Astronomical Association. Meanwhile, as a result of these advances, we have begun to feel ourselves in a position to attack the problem of rational interpretation, based on the data so far accumulated. Much has, in fact, already been accomplished in this direction, and it is satisfactory to find that the theories are beginning to stand the crucial test of prediction.

To summarise all that is so far known with certainty is not altogether easy, for many of the results of observation, doubtless in most cases quite trustworthy, still lack that general confirmation which would justify us in accepting them with complete confidence. However, the following would probably be accepted on all hands as a fair statement of the present condition of definite knowledge concerning Mars.

(1) The fact of the general permanence of the larger dark markings has been established, and their positions and outlines have been determined with considerable accuracy. In other words, we are in a position to construct a very recognisable map of the planet, as regards its main features.

(2) As a result of the above, it has been possible to ascertain the inclination of the planet's axis within a few minutes of arc, and to determine the rotation period within less than a tenth of a second of time.

(3) The size and rate of diminution of the polar caps has been shown to bear a definite relation to (*a*) the progress of the Martian seasons, (*b*) the distance of the planet from the sun, and (*c*) the extent of solar radiation as indicated by the sun-spot cycle. There is now general agreement that the caps must represent frozen water, the alternative of carbon dioxide, suggested some years ago, being for many reasons untenable.

(4) The large dark markings, while in general permanent in position and outline, are known to

undergo changes in intensity, both general and local. Some of these changes of intensity are clearly seasonal and regular, while for others no definite period can yet be assigned. They are probably of a secular or irregular nature. Some typical examples are shown in Figs. 2-4. Changes of colour, of seasonal origin, undoubtedly occur, but the regularity of these has not been satisfactorily demonstrated, and all the markings do not appear to share the same changes.

(5) Both dark and light regions of the planet are subject to temporary obscuration by patches of (*a*) white and (*b*) yellow material. The former, which occur most frequently near limb or terminator, have been variously ascribed to cloud, fog, snowfalls, or hoar-frost; the latter to cloud, dust-storms, or blown sand. We are, however, not yet justified in definitely attributing a particular obscuration to any one of these causes, though probably all are in operation at some time or other.

(6) Apart from the larger markings, the existence has been established of an intricate system of finer details, the exact form of which is still uncertain, though there is not the least doubt as to its objectivity.

(7) Finally, satisfactory photographic confirmation has been secured of practically all the above results.

Further elaboration here of all the sections of this summary is not necessary, but special reference should

best qualified to judge. In the case of objects whi lie so near the limits of visibility, factors of a climati instrumental, and personal nature are bound to ent very largely into the matter, and there is consequent room for much difference of opinion. The "canals having been seen and drawn as fine lines by experienc observers using apertures of 36 and 40 inches und good climatic conditions, t failure to see them with somewhat smaller aperture in less favourable position does n carry an overwhelming amount weight; and in any event suc evidence is purely negative. O the other hand, it does not see that the linear character of t markings in question has yet bee completely demonstrated. N doubt the decision must ult mately come from the large ape tures, but it is an unfortunate fa that the ideal combination of large and perfect instrument, first-rate climate, and a thoroughl efficient and trustworthy observe who is also a finished draft man and entirely free from th bias of preconceived ideas, has never yet been attaine The evidence of photography cannot be regarded a conclusive in either direction, though it has at leas proved the objectivity of detail that is approximatel linear. Since, however, it is impossible as yet t obtain a distinct photographic image of any feature that are beyond the visual reach of an eight-inch tel

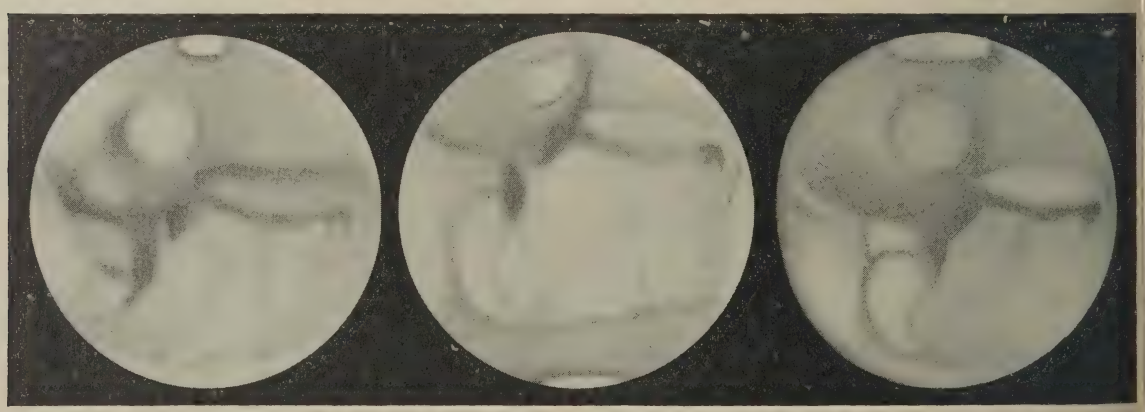

FIG. 2.—Mars. September 1909.
Note great development of Lacus Moeris, considerable breadth and intensity of Pandoræ Fretum, and darkness of M. Hadriacum as compared with Hellespontus. North end of Syrtis Major pointed.

FIG. 3.—Mars. July 1922.
Lacus Moeris only moderately developed as a mere continuation of Nepenthes-Thoth. Pandoræ Fretum narrow and faint, being far less prominent than Sinus Sabæus. Sinus Furcosus darker than the latter. Hellespontus very dark. North end of Syrtis Major blunt.

FIG. 4.—Mars. July 1924.
Lacus Moeris poorly developed. Pandoræ Fretum scarcely visible as a separate marking. Deucalionis Regio very pale as compared with area to the south of it. Hellespontus darker than M. Hadriacum. North end of Syrtis Major more pointed than in 1922.

be made to the sixth, since under this is included the so-called "canals," which have loomed so large in the more recent history of Martian observation. There seems to be a widespread impression, among those not in direct contact with the subject, that the existence of fine linear markings on Mars has been definitely and finally disproved. Actually, the question still remains entirely open in the opinion of those

scope, it follows that a really narrow line, if recorde at all, can only appear as a diffuse marking on th plate, so that we are still left in doubt as to its tru structure.

It is, perhaps, unfortunate that so much time an effort has been expended on this difficult question o the finer detail, especially with instruments that ar in any event inadequate for a final decision. Observer

apparently beginning to realise this, and more attention is now being paid, and that more profitably, to the less doubtful subject of changes in the large markings. This work is well within the compass of the instruments generally to be found in the hands of amateurs, who would do well, in the present writer's opinion, to leave the finer details to the larger apertures. In thus getting back to the partially neglected study of the more conspicuous features, we shall be correcting the mistake of attempting to run before we can walk. A good beginning has been made, but it is well to realise that it is no more than a beginning, and it will probably be many years before sufficient data have been accumulated to enable us to judge of the soundness or otherwise of current theories.

In recent years there has been much speculation as to the possible climate and temperature of Mars, and the density and composition of its atmosphere. This sort of thing is apt to blind us to the cold fact that our actual knowledge of these things, if knowledge it can be called, is still exceedingly vague, uncertain, and even contradictory. In view of this, the free and confident use of such definite terms as "cloud," "fog," "hoar-frost," and "vegetation" would seem to be somewhat premature, and liable to check progress by giving rise to a false impression of finality in our deductions. However eager we may be for a quick explanation of observed appearances, we cannot better serve the interests of research than by keeping an open mind.

Obituary.

Prof. James Seth.

In Prof. James Seth, who died of failure of the heart on July 24, at the age of sixty-four years, Edinburgh has lost one who belonged to the great race of Scottish professors. Educated at George Watson's College and the University of Edinburgh, he went through a complete course of training for the ministry at the Free Church College. Turning from his original intention to his true vocation, he studied philosophy at Leipzig, Jena, and Berlin. In 1883 he became assistant to Prof. Campbell Fraser in his own University, and two years afterwards was appointed professor of philosophy at Dalhousie College, Halifax, Nova Scotia. In 1892 he accepted a chair in Brown University, Providence, Rhode Island, and four years later the Sage professorship of moral philosophy in Cornell University. From Cornell he was recalled in 1898 to succeed Prof. Calderwood in the chair of moral philosophy in Edinburgh.

During his twenty-six years' tenure of this post, Seth made a place for himself in the life of the University and the city that would bear comparison with the most distinguished in the long line of his predecessors. Not as well known as his elder brother and colleague, Andrew Seth Pringle-Pattison, he had the same high standard of scholarship in philosophy and much of the same distinction of style in his written work. The writer of the "appreciation" in the *Scotsman* on the day after his death, remarked on "the unique partnership so fruitful in good results" between the brothers. For the rest, his methods as a teacher and the place he took in the life of the University and the city were entirely his own. Endowed with great readiness of speech and a singular power of entering into the minds of his students, he was able in spite of the size of his classes to perfect a form of catechetical instruction which was the delight of his students and made "Prof. Jim" for a quarter of a century one of the most popular teachers in Scotland.

On the other hand, related by his subject of moral (which, on his interpretation of it, meant also political) philosophy to the civic life of the community, Seth took the warmest practical interest in all advanced movements. He held that "it is for the State to emancipate from the slavery of social conditions the toiling masses of society, to endow those who are citizens only in name with a real ethical citizenship—the franchise of a complete and worthy human life," in a word, "to co-ordinate the industrial with the ethical life." It was in such a "regulative socialism" that he found the *via media* between individualistic and communistic extremes. In the same spirit he interested himself in the Settlement and kindred movements and took a leading part in the establishment of a course of study in social science with the view of linking these more closely with the University. His wide connexion with America and the Continent and his generous hospitality made the bachelor home, which he shared with his younger brother John, a rendezvous of scholars from all parts of the world as well as of his more intimate friends in Britain. It was altogether in harmony with the genius for friendship that was so marked a feature of his character that he died in the course of a round of calls upon acquaintances who were themselves in trouble. *Sic vivamus ut sic moriamur.*

Seth's chief contributions to philosophy were his book upon "Ethical Principles" (1894), now in its fifteenth edition, and the volume in the series Channels of English Literature on "English Philosophers and Schools of Philosophy" (1912). In the former of these he expounds in a masterly way and with a fine sense of the power of the English language the sober form of idealism with which, by his own teaching not less than that of Campbell Fraser, Simon Laurie, and his brother, philosophy in Edinburgh has been identified. It differs, as the student of philosophy knows, from that associated with the great sister University in the West under the influence of Edward Caird and Henry Jones, chiefly in the emphasis it lays on separate will and personality as an ultimate category and its more definite teaching on the subjects of theism and individual immortality. This is not the place for comparison and criticism, but we touch here on what is probably the main issue between Idealistic philosophers at the present time and we can ill spare the help which so open-minded and "synoptic" a thinker as Prof. Seth might have rendered in clearing it up in the greater leisure of the retirement to which he had been looking forward. We may hope that he has left behind him some record of his maturest thought upon it that may yet be published.

J. H. Muirhead.

Dr. R. H. Jude.

Much regret was felt in scientific circles at the death of Dr. R. H. Jude on June 1. Until his retirement during the War, Dr. Jude was for more than thirty years in charge of the Mathematical and Physical Department of Rutherford College, Newcastle-on-Tyne, and he played a very prominent part in the higher education particularly of young engineers on Tyneside, many of whom now occupy prominent positions in the engineering world. For several years he had been a victim of diabetes, but, in spite of ill-health and progressive deafness and blindness, he retained to the end a brave fortitude in his outlook, an active and a clear mentality, and his letters rarely lacked in that spark of dry humour so characteristic of him in earlier years.

Dr. Jude was born on December 31, 1853, at Camberwell, and after receiving his early education at King's College School, Strand, he gained a scholarship and proceeded to Christ's College, Cambridge, where he took the B.A. degree. In 1876 he was bracketed 18th Wrangler in the Mathematical Tripos, and the following year he obtained a first class, with a special mark of distinction, in the Natural Science Tripos. One year later, in 1878, he gained the degree of D.Sc. of the University of London, and for a short period after graduation he also studied at the University of Heidelberg.

During his long association with Rutherford College, Dr. Jude played a large part in the development of the scientific side of that institution. In the words of one of his former colleagues, he had "a profound and ready grasp of his subjects, and a singularly lucid power of exposition"; but above all he wielded "a quickening influence over his students, based on a lively sense of sympathy with both their difficulties and their aspirations, and he so mingled these qualities with a forestalling courtesy as to combine in a rare degree all that gives efficiency and charm to a lecturer." Whilst he took a keen and helpful interest in and had unbounded patience with his elementary students, Dr. Jude was untiring in his efforts to develop the advanced work of his department. In addition to advanced courses in mathematics, he also instituted courses in higher mathematics for engineers and a tutorial class for advanced students, held on Saturday afternoons. Those of us who were privileged to attend these classes saw him at his best, and found in him a friend to whom no labour was a trouble, so long as it might benefit his students. Not merely content with solving his students' difficulties, he often pursued their problems and derived interesting and original results, and although Dr. Jude did not publish many original papers in mathematical and physical subjects, this was undoubtedly due to the monopolisation of his time by teaching duties and problems arising from them. Nevertheless, we owe a great debt to him for his admirable treatise on physics, and for his books on elementary and advanced electricity and magnetism, all of which have been favourably reviewed in these columns. By their clearness and originality of treatment these books have done inestimable service to British students of science. Much of the apparatus described in them was of his o design.

In his youth, Dr. Jude acquired proficiency in Fren and German, and could converse freely in eith language. Moreover, in addition to Greek and Lati he made a study of Arabic. Quite late in his acti career, and in connexion with the translation of one his books into Russian, he took up the study of th language so that he might be able to look over t proofs of the translation. But perhaps the mo remarkable of his linguistic achievements took pla after his retirement. Living in Wales, and constant hearing it spoken, he obtained a considerable knowled of Welsh, in spite of failing vision, and was able converse freely with the villagers.

By his kindly, unobtrusive, and gentlemanly bearin Dr. Jude was endeared of all with whom he associate His active life was spent in the service of others. H had much to give, and gave of it unstintingly. O sympathy goes out to his widow, for whose unfailin encouragement and help he was ever grateful, especial in later years of failing sight and hearing.

Robert W. Lawson.

Prof. Albert Hesse.

The issue of the *Chemisches Zentralblatt* for May announces the death at Berlin—Wilmersdorf—of Pro Albert Hesse, who was editor of that journal from 19 until 1923. He died on May 10, after a long and painf illness, at the comparatively early age of fifty-seve The systematic co-ordination and abstracting of pu and applied chemical literature was the main achiev ment by which Dr. Hesse is known, and his great succe in this field has been and is still of great service to t chemist. The fusion of the *Chemisches Zentralbl* with the abstract journal of the *Zeitschrift für a gewandte Chemie* in 1919 was a great achievement f Dr. Hesse, and this union will help also in the solutio of the problem, yet unaccomplished, of including a abstract of the current patent chemical literature the world.

Before concentrating on editorial work Dr. Hes was an active chemist both from the academic ar industrial aspects. He was a pupil of Wallach, ar made a close study of the ethereal oils. His studies o sesquiterpene alcohols and the odoriferous constituen of flowers, including jasmin, rose, ylang, tuber, ar orange-blossom, and the synthesis of camphor we among the problems which at different times occupie his attention. He was associated for some time wit the famous firm of Heine and Co. of Leipzig, and h name occurs in many patents connected with essenti oil.

In addition to his editorial work and his contributio to patent literature, reference may be made to tw publications of a more economic character. Jointl with Prof. Grossmann he wrote a report entitle "England's Trade War and the German Chemic Industry," and in 1909 in the Wallach-festival publica tion he dealt with "The Development of the Ethere Oil Industry in the last 25 years in Germany."

J. Reilly.

Current Topics and Events.

ANYTHING that will cheapen the cost of the electrification of our railways deserves serious study at the present time. In the United States, a continually increasing number of automatic sub-stations are being employed in electric traction. It is interesting, therefore, to notice that in the extension of the London Electric Railway from Hendon to Edgware, which opened for traffic on August 18, there is a completely equipped automatic sub-station. Although there are several of these stations in Great Britain in connexion with lighting networks, this is the first to be used for traction purposes. The building has been designed for three 1200-kilowatt rotary converters with all the necessary control gear and accessories. The sub-station gets a 10,500-volt three-phase supply from the Lots Road Generating Station at Chelsea, the frequency being $33\frac{1}{3}$. It is situated at Burnt Oak, which is one mile from the Edgware terminus and four miles from the manually operated sub-station at Golder's Green. To start a rotary converter at Burnt Oak, it is only necessary to close a switch at Golder's Green, all the subsequent operations being automatic. Cooling air for the transformers is supplied by a centrifugal blower. The automatic devices protect the machines in all conditions of overload. For example, when the load is too heavy, the circuit breaker opens and a resistance is inserted in the machine circuit and the rotary is disconnected from the supply mains. After a short interval the circuit breaker closes again and connexion is re-made. If the fault has been cleared, normal operation is resumed, but if not, the same sequence of operations happens again. If this happens a fixed number of times, the breaker is automatically locked and an engineer must be sent to investigate and remove the fault.

AT the conversaziones of the Royal Societies of Western Australia and New South Wales, held on June 28 and July 2, fitting celebrations were made of the centenary of the birth of Lord Kelvin. At the former there was an extensive exhibition of Kelvin apparatus and relics, including a series of photographs and engravings of the Old College at Glasgow. Lecturettes were given illustrating various phases of Kelvin's life and work. Their titles were "Gyroscopes," "The Atlantic Cable," "The Age of the Earth," "Glacier Motion," and "Solar Heat." At Sydney, Prof. H. S. Carslaw—an old pupil of Kelvin's—gave a memorial oration. He recalled the fact that two of the most famous periods in the history of mathematics in England were the age of Newton and the years during which the school of mathematical physics arose and flourished in Cambridge. Of the great names of that period without doubt the greatest was Kelvin. He had made valuable contributions to almost every branch of mathematical physics, and was the greatest pioneer of the age of electricity. It was peculiarly fitting that Australians should commemorate Kelvin, for his work on navigation made it much safer for them to cross the 12,000 miles of ocean which separated them from the homeland. The age of steam has done much for Australia, but the age of electricity has already done more.

SCOTLAND has never yielded, nor is it likely to yield, the range of prehistoric civilisations which successively flourished in southern Britain, for the incidence of the Ice Age markedly reduced the habitable period in the northern kingdom. Yet it is possible that Scotland may furnish evidence on an important and obscure stage in the more recent history of prehistoric man, namely, on the transition from Azilian to neolithic culture. So far, the shell-mounds and kitchen middens of Oransay and elsewhere have given clues to one culture or the other, but none has shown a continuous habitation throughout the critical period. It is our belief that the places most likely to reveal such are the caves, and since these have been very imperfectly surveyed in Scotland, each new cave-excavation not only deserves commendation and encouragement, but raises hopes of outstanding discoveries. On the Mull of Kintyre, about four miles south of Campbeltown, the Kintyre Antiquarian Society has, with the assistance of Mr. L. M'L. Mann, set about excavating St. Kieran's Cave. Their findings, recorded in the *Glasgow Herald* of July 31, included an incised symbol clearly of Christian origin, flint implements, bone objects, and a human skeleton, buried in a short cist, and accompanied only by a worked flint. The skull is compared conjecturally with the famous dolichocephalic skulls of the Oban caves. The digging revealed the presence of several layers of habitation, but the details given are not sufficient to indicate the ages of the deposits, and the results of expert examination of the relics will be awaited with interest.

MR. J. H. MAIDEN, who for nearly twenty years has been government botanist of New South Wales and director of the Sydney Botanic Gardens, has recently retired under the age-limit. Born at St. John's Wood, London, in 1859, Mr. Maiden went to Sydney about forty-five years ago. Before leaving England he had studied botany under Prof. R. Bentley and Prof. D. Oliver, and shortly after settling in Sydney was employed in the Technological Museum there, becoming curator and secretary in 1882, after a year's service as acting curator. While holding these offices his botanical work was chiefly connected with economic plants, on which he contributed numerous papers to journals. In 1889 he published his well-known book: "The Useful Native Plants of Australia," and in 1890 appeared the first of the three editions of his "Wattles and Wattle-barks." During Mr. Maiden's directorship of the beautiful Botanic Gardens, Sydney, to which he was appointed in 1896, many improvements in them have been effected, and he had the satisfaction of seeing the erection of the fine new building in which are accommodated the Botanical Museum and Herbarium; this was completed in 1901. Holding important administrative and advisory posts it might be supposed that he would have had little time for authorship. Yet by his writings he has won a world-wide

reputation and a high position among the greatest botanists of his adopted country. "A Critical Revision of the Genus Eucalyptus," now in its seventh volume, is in itself a fine achievement. "The Forest Flora of New South Wales," of which seven volumes have been completed, is another. Mr. Maiden is also the author of several other independent works and of a multitude of papers in journals of societies and other publications. He has served a number of the scientific societies of Australia in various offices, and was president of the Royal Society of New South Wales in 1896–97 and again in 1911–12. Mr. Maiden became a fellow of the Linnean Society of London in 1888, and in 1915 received its Gold Medal. He was elected a fellow of the Royal Society in 1916, and in the same year was appointed to the Imperial Service Order. We look forward to the completion of his valuable Revision of the Genus Eucalyptus during the coming years.

In a circular letter dated July 10, M. Sampaio Ferraz, director of the Meteorological Service of Brazil, urges the publication of reports of abnormal weather or abnormal wind circulation in some central publication, say the *Meteorological Magazine*. The abnormal wind and excessive rain experienced in Brazil during April and May of this year are quoted as a type of the information which might be collected in this manner. M. Ferraz suggests that all information for a particular month should appear in the same number of the *Meteorological Magazine*. The scheme put forward appears to us to be highly desirable, and it is to be hoped that either the *Meteorological Magazine*, or the Royal Meteorological Society, through its Quarterly Journal, will be able to make arrangements to publish such reports as are suggested from all the meteorological services and institutes of the world, two or three months in arrear. In the past, the publication of reports of abnormal weather conditions has been left largely to the *Meteorologische Zeitschrift*, but it is highly desirable to make a more systematic collection of such data, and to make them available in an English periodical.

The August issue of the *Scientific Monthly* contains the address of Dr. Arthur D. Little to the Engineering Division of the National Research Council of the United States, under the title "Research: the Mother of Industry." After a short account of the great advances in industry during his own lifetime, he directs particular attention to the developments of the decade 1890–1900, during which Hall brought out the aluminium process, Acheson made carborundum, Willson calcium carbide, Diesel invented his engine, Cross and Bevan made artificial silk, Little himself produced cellulose acetate, Röntgen discovered the X-rays, Becquerel radioactivity, Madame Curie radium, and Marconi sent a wireless message across the Bristol Channel. On nearly every one of these discoveries an industry has been founded, and Dr. Little points out that while in the past the United States has prospered because of its cheap land and abundant raw materials, it can only maintain its position in the future by making use of every assis ance science can afford, and that industry must in i own interest support research generously.

The value of chemical evidence in archæology generally known, and there are many examples mistakes which have arisen from lack of chemic knowledge; for example, the description of early met objects from Mesopotamia as "bronze," whereas i reality they are almost pure copper. In a very bri note in the *Cairo Scientific Journal* for July, Mr. Lucas gives some further examples. The blac appearance of mummies is generally attributed to th use of bitumen, whereas it is either the result of change of the flesh itself or of resin, or gum-resi which has blackened by natural processes. N evidence has yet been found of the use of bitumen mineral pitch, although they may have been used i Ptolemaic times. Castor oil has been described a honey and as natron, alkali used in glass-making ha been described as potash though it was generally not always soda, and the presence or absence of coba as a blue colour for glass and as a pigment has bee asserted and denied without any chemical evidenc Most of the archæologists who have made really valu able progress have paid attention to the assistanc which can be given by chemistry, and in future i may be assumed that the services of the chemist wil be called in even more extensively than in the past.

In the *Empire Review* for August, the problem the mentally defective is raised again. It is a proble which is always with us, but which for that ver reason is likely to be overlooked. Discussions on th subject usually resolve themselves into heated oppos tion to all the suggested schemes for dealing with th defective, or into a fatalistic resignation to the futilit of all schemes. Miss Nelly Burdett pleads for th reanimation of public interest in the subject, whic shall lead to more earnest efforts to put these peop into such a position that they can be useful membe of their own society, since by their defect they a debarred from adapting adequately to general societ She points out the disquieting fact that with ou present system of half-hearted treatment, the rank of the mentally defective are being increased. I 1906 it was estimated that one person in every 25 was mentally defective. Now it is one in every 20 A Royal Commission appointed in 1904, after fou years' work, made recommendations which have no yet been realised. A point of considerable interes not dealt with in this article, is that emotional cor flict may mask itself in some form of mental defec and much later trouble could be spared by suitabl treatment and understanding from the beginning.

At the conference on Illuminating Engineering hel at the British Empire Exhibition on August 12, paper was read by Mr. L. Gaster summarising develop ments at the International Conference on Industria Hygiene, and the meeting of the Internationa Illumination Commission recently held in Geneva The former afforded a good opportunity of interestin experts on hygiene in illumination, and the importanc of good industrial lighting in the interests of th

alth and safety of workers was freely recognised. was suggested that the International Illumination mmission should bring before the International abour Bureau of the League of Nations problems industrial lighting, etc., with a view to their being udied by the Governments of the respective coun- ies. Industrial lighting also formed the subject of uch discussion by members of the International lumination Commission. A feature of interest is he large number of scientific and industrial bodies hich co-operate with the American Illuminating ngineering Society in the revision of their codes of chool and factory lighting. Arrangements have been ade for the National Research Council to supervise searches on the results of better lighting. These cts were mentioned to illustrate the desire for co- peration in the United States and the recognition y manufacturers and gas and electricity supply ndertakings that researches, in order to carry weight ith the public, must bear the impress of scientific nd impartial authority. After describing the methods dopted in America for promoting public appreciation f the benefits of good lighting, Mr. Gaster urged the eed for a comprehensive scheme in Great Britain, in hich all interested in illumination could join. A esolution approving the proposal of the Illuminating ngineering Society to initiate such a scheme was assed unanimously. A paper on "Illumination of lighways from the Motorists' Point of View" was ead by Mr. E. H. Fryer, and there was also an nteresting discussion on the methods of lighting dopted at the British Empire Exhibition.

A FULL report of the International Meteorological onference of Directors and of the meeting of the nternational Meteorological Committee at Utrecht, eptember 1923, an account of which appeared in NATURE of October 6, 1923, p. 523, has recently been ssued as Publication No. 112 of the Koninklijk Neder- ndsch Meteorologisch Institut. The volume consists f 191 pages. At the meeting in London, September 921, it was arranged that the next meeting should be eld at Utrecht. The president was Sir Napier Shaw, nd the assembly represented 20 countries, including, n addition to Europe, Argentine, Brazil, India, Japan, nd New Zealand. There was a very copious agenda, he rapid progress of meteorology of late years render- ng international understandings and arrangements ssential to its further advancement. Land and narine meteorology over the whole globe were con- idered as well as upper air observations, and the eneral collection and distribution of obtained results. The Appendices give a large amount of information, considered internationally, and afford much material or quiet study. The discussion includes terrestrial nagnetism and electricity of the atmosphere, solar and errestrial radiation. Special consideration is given o the exploration of the upper air, the arrangement of dates for international ascents of pilot-balloons and ballons sondes, and a time-table of issues by radio- telegraphy in connexion with weather telegraphy and weather forecasting. The subjects include marine meteorology with its important considerations of world-wide interest, réseau mondial, agricultural meteorology, the propagation of sound by means of explosions, and the study of clouds. These inter- national meetings lead to essential uniformity in methods of observation and discussion and aid much in the extension of observations for land and sea areas. For weather forecasting and for considerations of physical meteorology on land or sea as well as in the air above the surface of the globe, trustworthy and comparable data are available—the aims and objects being arranged by personal contact among those interested and responsible for the world's meteorology.

THE *Chemiker Zeitung* announces that Prof. W. J. de Haas, of Groningen, has been appointed to succeed Prof. H. Kamerlingh Onnes, of Leyden, who has resigned.

AT the annual autumn meeting of the Institute of Metals to be held in London on September 8-11, Mr. W. M. Corse, of the National Research Council, Washington, D.C., will lecture on "Recent Develop- ments in Non-Ferrous Metallurgy in the United States, with Special Reference to Nickel and Alu- minium-Bronze." Visitors' tickets for the meeting can be obtained from the Secretary of the Institute, Mr. G. Shaw Scott, 36-38 Victoria Street, Westminster.

AT the monthly General Meeting of the Zoological Society of London held on August 13 it was reported that the number of visitors to the Society's gardens during the month of July had been 266,559, showing an increase of 85,538 as compared with the corre- sponding month last year. The total number of visitors to the Gardens since January 1 had been 1,079,608, an increase of 249,239. The number of visitors to the Society's aquarium since its opening on April 4 had been 316,347.

A SURVEY of the Great Barrier Reef area has been undertaken by the Commonwealth Government of Australia, and the naval sloop *Geranium* has been detailed for the work. The vessel will have a seaplane attached for general help and work in the survey, and a preliminary flight around the coastline of Australia was recently completed with the view of deciding the kind of assistance which can best be afforded from observa- tions in the air. The commander of the *Geranium* is a member of the Barrier Reef Committee of the University of Queensland, and he will take with him two scientific investigators attached to the Committee.

A PRIZE for the physiology and pathology of alti- tude has been founded by the Alpine Sanatorium of Semmering, Austria. One thousand gold krone are offered to the author of the best work accomplished or published in the last two years, which has extended our knowledge of the action of alpine climate on man. The prize is intended in the first instance for Austrians, but foreigners can also be considered if their work has been carried out in Austria. Printed or typed papers should reach the Kanzlei of the Akademie der Wissenschaften, Wien I., Universitäts- platz 2, before December 31, 1924. Some notable English reports both from the Andes and the Himalaya deserve to be laid before the commission of judges, even if they may have to be marked not for competition.

THE communications of the Society of German Men of Science and Physicians—Gesellschaft Deutscher Naturforscher und Ärzte—are now distributed monthly with *Die Naturwissenschaften*. The *Mitteilungen* give general information about the Society. Subscriptions have been reduced to a minimum of three marks; those who can are asked to give more. The 88th meeting is to be held at Innsbruck, Austria (Sept. 21-27). The president-elect, Dr. Richard Paltauf, professor of pathology in Vienna, died on April 21. Some of the chief addresses at Innsbruck will be by Dr. Hoche on the body-mind problem, Dr. Hess on the physiology of work, Dr. Frisch on the senses and language of bees, Dr. Sommerfeld on atomic researches, Dr. Penck on the aspect of the Alps. Those intending to take part in the Innsbruck meeting should communicate with Prof. D. A. Defant, Büro der Naturforscher Versammlung, Physik. Institut, Schöpfstr. 41, Innsbruck.

THE Castner-Kellner Alkali Co., Ltd., has issued recently a number of informative pamphlets dealing with some of the chemical products which it manufactures. Among these is sodium perborate, which is used for bleaching textiles, oils, fats, waxes, and foodstuffs. In the solid state this substance is quite stable, but on solution in water it yields hydrogen peroxide, caustic soda, and borax, the last named acting as a water-softener. The formation of caustic soda might be harmful, but can be readily obviated b adding sodium phosphate or bicarbonate, or a pu mineral acid. The pamphlet entitled "Chlorine ar Chlorine Products in relation to Public Health describes the manifold applications of liquid chlorin bleaching powder, and sodium hypochlorite. Liqu chlorine is being used increasingly for sterilising po able water, and it is not generally known that a lar proportion of the London water supply is now treate with this substance in the ratio of 0·5 part of gaseo chlorine to one million of water, whereby the water improved bacteriologically about one thousand time It is well known that diseases may be contracted fro the water in public swimming-baths; 1-3 parts chloride of lime per million of water, applied ever 1-2 days, will effectually sterilise the water. Oth applications are for sterilising canal or river wat before use in condensers at power-stations, and f disinfecting streets, sewage, the farm and the kenne A third pamphlet contains, *inter alia*, directions f using bleaching powder, calcium hypochlorite an sodium hypochlorite solutions to bleach textil (other than wool), artificial silk, and paper pulp, wit or without previous scouring with alkali and a solver such as trichloroethylene. Bleaching agents co taining chlorine are now in use for bleaching an desulphurising mineral oil, and for converting u saturated hydrocarbons in such oil into saturate hydrocarbons.

Our Astronomical Column.

THE PERSEIDS OF 1924.—Mr. W. F. Denning writes: "From observations made at various stations, it appears that the shower has been less abundant than usual. On the important night of August 11, the weather was unfavourable and only enabled a few meteors to be seen through breaks in the clouds. At Ashby, Lincolnshire, Mr. King, watching occasionally a partially overcast sky between $10^h\ 29^m$ and $13^h\ 58^m$ G.M.T., saw 28 meteors, of which 19 were Perseids, from a radiant well defined at $46° + 57°$. At $13^h\ 20\frac{1}{2}^m$ a splendid Perseid several times brighter than Venus was observed shooting from $30° + 52\frac{1}{2}°$ to $26° + 50\frac{1}{2}°$. A brilliant Perseid was also seen from Warwick Road, London, S.W., and from Greenwich, S.E., on August 12 at $9^h\ 42^m$ G.M.T. It was about three times as bright as Venus and left a luminous trail for about ten seconds. The direction of the flight was from α Ursæ Majoris towards α Comæ Berenicis, so that the object was evidently a very fine Perseid. Further observations of the two large meteors referred to above would be valuable."

AN ANTI-RELATIVITY THEORY.—Articles in the July and August numbers of *Scientia* by Prof. La Rosa contain a daring suggestion as to the cause of variability in stars, including the outburst of Novæ. Few are likely to accept the author's suggestion as a *vera causa*, but the articles are worth reading as a study of the consequences that would follow from his assumptions as to the laws governing the speed of light.

Prof. La Rosa rejects not only the Einstein postulate as to the constancy of the measured speed of light, but also the previous postulate that the speed is conditioned by the medium conveying the light-waves. In fact, he reverts to the corpuscular theory, supposing that the speed of the corpuscles is the resultant between the speed of the luminous body and that of the emission of corpuscles. Taking, for example, a star moving with a speed of 60 miles per second in circular orbit the plane of which passes through the sun the difference between the speeds of emission at the tw elongations is 1/1500 of that of light, and if the tim between the elongations were (say) 2 months, and th star 250 light-years from the sun, the light emitted a the two elongations would reach us simultaneously There would thus be a rhythmic increase and diminu tion in the amount of light received during th revolution. Novæ are explained by supposing ver eccentric orbits of cometary form so arranged as t give a great concentration of light in the neighbour hood of perihelion.

PROPER MOTIONS OF THE HYADES.—Memoir No 35 of the Kapteyn Laboratory at Groningen, by th Director, Prof. van Rhijn, deals with the prope motions of the Hyades stars, based on photograph taken at Helsingfors. It contains a full discussio of the measures and reductions and a catalogue of 39 proper motions. The final mean annual prope motion of the cluster is given as 0·102″ in Positio Angle 102°. It is not difficult to separate the cluste stars from the non-cluster ones by their motion this appears clearly when the motions are plotted as series of dots the abscissæ and ordinates of whic indicate the motion in x, y respectively.

The density of non-cluster stars is found to b somewhat less than in other regions of the sam galactic latitude, and it is noted that the sam peculiarity has been found in other cluster regions We may conjecture that the cluster stars are sur rounded by dust-bearing regions, which absorb som of the light of stars in the background. The presenc of such dust round the Pleiades stars is shown b their accompanying nebulæ, the spectra of whic appear to indicate that they are dust-clouds reflectin the star light.

Research Items.

Poisons and Witchcraft in Papua.—In the August issue of *Man* the Rev. R. Lister Turner describes the methods in the use of poison in witchcraft in Papua, which exhibit a close resemblance to those practices recorded by Dr. Codrington as being followed in the island of Florida by the Melanesians. This Papuan custom, which is known by the name of "Vada," consists in stunning the victim with a club and then forcing poison plants down his throat. A magical formula is repeated over the victim and he is gradually brought back to consciousness. Later he dies. It is said that an alternative method is to place the poison in a cut in the thigh, which is healed magically so as to leave no trace of the wound. Three poisons are believed to be employed—"Matua" and "Tua," which are plants, and "Gavroa," a worm with yellow stripes; but owing to the secrecy which is essential to the success of the "Vada," it is not possible to say more than that there is a probability that poisons are used. A method in which poisons are not used has come under the notice of the authorities. In this the abdomen of the victim is pummelled with cobble stones after he has been rendered unconscious. The result in one case was death from a broken spleen.

The Inhabitants of New Caledonia and Neanderthal Man.—Prof. Fritz Sarasin has made a detailed comparative study of the osteology of the New Caledonians and Neanderthal man, of which the results are published in *L'Anthropologie*, xxxiv., Nos. 3-. He finds that in a large number of their skeletal characters the New Caledonians show a closer affinity to Neanderthal man than do Europeans; but, on the other hand, in certain features they are even more primitive than the Neanderthal group. Among these are irregularities in the region of the pterion, a more pronounced prognathism and the more simian conformation of the nasal skeleton. There are, however, a number of divergences in the two groups. The New Caledonians, for example, have a more vaulted cranium, rectangular orbits, and the radius shows little or no curvature, while all the bones of the skeleton are less robust. The general conclusion is that the New Caledonians form one of a closely-related group, including Australians, Tasmanians, and other Melaneans, which is more primitive than the fossil representatives of *homo sapiens*, Piltdown man being set aside as still indeterminate. It resembles closely the primitive ancestor of existing races, Rhodesian man possibly being the proto-Australian type, and the connecting link between the Austro-Melanesian group and a pre-Neanderthaloid ancestor.

Precursors of the Japanese Earthquake.—In two earlier papers the late Prof. Omori described semi-destructive earthquakes at Tokyo in 1921 and 1922, and, in a posthumous paper (*Seismological Notes*, No. 4, 1924) he refers to the strong earthquake of January 14, 1923. The focus lay some distance to the north of that afterwards in action on September 1, lying about 30 miles N.N.E. of Tokyo. From the duration of the preliminary tremor he assigns to the focus the unusually great depth of about 30 miles. In an appendix dealing with future earthquakes in Tokyo (written before the great earthquake) he ventures on some predictions which, unfortunately, have not been verified. "Tokyo," he says, "may be assumed to be free in future from the visitation of a violent earthquake like that of 1855, as the latter shock originated right under the city itself, and as destructive earthquakes do not repeat from one and the same origin, at least not in the course of 1000 or 1500 years," and "a great suboceanic earthquake off the coast of Izu or Awa-Kazusa peninsula . . . is not likely to occur for at least some 60 or 70 years to come." Yet it was in the latter district that the recent earthquake had its origin.

The Action of Pituitary Extracts.—In a recent paper in the *Quarterly Journal of Physiology*, L. T. Hogben and W. Schlapp (vol. xiv. p. 229) have studied the effects of pituitary extracts on vertebrates other than mammals, with the view of finding whether there is any evidence of the existence of independent components showing vascular activity in the extracts. Adrenaline produces a rise of blood pressure in all four classes of air-breathing vertebrates, but pituitary extracts in physiologically significant doses have no such effects on the blood pressure of the reptile or amphibian, there being in fact a fall of pressure in birds and reptiles, though corresponding doses of the same preparations produced pressor effects in mammals.

Insulin from the Cod-fish.—Dr. H. W. Dudley, in the current number of the *Biochemical Journal* (xviii. p. 665), shows that insulin may be obtained in large amount from the islet tissue of the cod-fish. The yield, even under unfavourable conditions, was as high as 13·12 rabbit units per gram, and probably more would have been obtained from absolutely fresh islets. It is estimated that the islet tissue of the cod contains, weight for weight, about ten times as much insulin as is present in mammalian pancreas. The material was collected from the Yorkshire shore fisheries in February and March, and placed in picric acid solution, which fixed the tissue and converted the insulin into a picrate. The insulin-containing picrate fraction was extracted with watery acetone, and the picrate converted into the hydrochloride by the method previously described by the author. The finding of such large yields of insulin in the islet tissue, which is structurally identical with the islets of Langerhans of the pancreas in mammals, furnishes us with very good proof that it is really in the islets of the pancreas that insulin is normally produced.

South American Non-marine Mollusca.—Dr. H. A. Pilsbry (Proc. Acad. Nat. Sci. Philad., vol. lxxvi.) has, under a common title, united four notes on South American non-marine Mollusca. The first deals with shells from Lake Titicaca, whence very few mollusca are known and nearly all of species confined to the lake. The varieties of *Planorbis andecolus* are specially described and figured photographically on an excellent plate. There are, further, four species of Littoridina, two being new, and a new species of Pisidium (*P. titicacensis*) which, if correctly figured, exhibits hinge characters differing from those usual to the genus. The second note, on South American genera of Ancylidæ, discusses four out of the five genera known from that continent, including a new genus, Anisancylus, founded with *Ancylus obliquus*, Brod. and Sowb., as type. Descriptions of two Brazilian Amnicolidæ, being new species of Idiopyrgus and Potamolithus, form the third note. A note on Pupillidæ collected by Dr. Baker in Curaçao and its dependencies in 1922 concludes the series. A new species and new sub-species are described. Text figures accompany all four notes.

Weather at Hongkong.—A report of the Royal Observatory, Hongkong, for the year 1923, prepared by the director, Mr. T. F. Claxton, has recently been

issued. In addition to the annual report, a Monthly Meteorological Bulletin is issued. Automatic records are obtained for most elements, and considerable care is exercised to secure the greatest accuracy. The monthly and annual values of the several elements are given in the December Bulletin, and in lesser detail in the Annual Report. The mean temperature for the year was 72°·5 F., which is 0°·6 above the normal for the past 40 years; the absolutely highest temperature was 92°·9 on August 4 (the highest on record for the 40 years is 97°); the lowest temperature was 45°·7 on January 4, whilst for the 40 years the lowest reading is 32°. Temperature was considerably above normal in March, November and December, and moderately above in April and May; in the remaining months it was nearly normal. The total rainfall for the year was 106·74 in., which is approximately 22 inches more than the normal for 40 years, the greatest fall in one day was 11·50 in. on October 31, when in a single hour the fall was 2·82 in. The maximum wind velocity for one hour was 106 miles on August 18, which is only 2 miles less than the highest on record; the maximum squall velocity on the same day was at the rate of 130 m.p.h., the highest on record. Tracks of typhoons and depressions in the Far East during the year 1923 are given, and the centre of the memorable storm of August 18 is shown to have passed over Hongkong, travelling westward from off the sea. The seismograms show that 141 earthquakes were recorded in 1923. In connexion with upper air research, 49 flights with pilot balloons were made during the year. Daily weather reports from surrounding stations are given in each Monthly Meteorological Bulletin.

A Theory of Super-Conductivity.—Herr E. Kretschmann, in the *Annalen der Physik* for June, develops a new mathematical theory of electrical conduction, and uses it to explain the phenomena near the absolute zero of temperature. He rejects the idea that the conduction electrons are moving in any kind of quantum orbit, and deals with them as a swarm, moving under the influence of an infinitely small e.m.f.; he concludes that the specific conductivity of a homogeneous isotropic metallic conductor is infinite, for a swarm with given velocity in the direction of the current, when and only when the mean retardation in this direction vanishes. This will be the case, according to the quantum theory, if none of the conduction electrons spring into the closed quantum orbits of the molecules of the substance. He supposes that near the absolute zero all the quantum orbits are occupied, so that the conduction electrons cannot spring into them. When the temperature rises above a certain critical point the exterior orbits "are broken up" by the thermal vibrations of the molecules; this apparently means that electrons in these orbits are thrown off in haphazard directions, and conduction electrons fall into the orbits after an interval, so that the average velocity of the swarm is diminished.

The Crystalline Structure of Solidified Argon.—Herr F. Simon and Fräulein C. von Simson describe, in the *Zeitschrift für Physik*, July 2, an X-ray investigation of solid argon, in which they employed the method previously used by them for hydrogen chloride. Liquid hydrogen was passed through the capillary tube of the apparatus to cool the surrounding argon to its freezing point. The lattice is cubic, face centred, with closest spherical packing; at $T=40°$ abs. $a=5{\cdot}42\pm0{\cdot}02$ Å, and the density is $1{\cdot}62\pm0{\cdot}02$. The density of the liquid at the melting point, 84° abs., has been found by Baly and Donnan to be 1·42. The atomic radius (Bragg's formula) is 1·92 Å, while the mean ionic radius of K^+ and Cl^-, which have the sa electron arrangement as argon, is 1·52 Å. It appe then that the atomic radius depends on the for acting between the atoms, and is smaller the lar the forces of attraction. The authors make use their results to study argon from the point of view the theories of Mie, Grüneisen, and Born. On approximate results can be obtained, as the data a incomplete; but it appears that the behaviour argon is different from that of the metals, in whi the exponent of the term representing attracti force at close range is $m=3$, while for argon it m be about 9.

The Intervals between the Optical Double and Triplets.—Prof. A. Landé contributes a pap to the *Zeitschrift für Physik*, June 24, in which deals with the relationship between the optic doublets and the X-ray relativity doublets. It cann be expected that the former should show the sa exactness in satisfying Sommerfeld's simple appro mate formula as that author has found in the ca of the X-ray spectra. In the latter case the process take place in the inner electronic spheres, where t conditions alter in the simplest (linear) manner wi increase of the nuclear charge, $+Ze$. The optic terms, on the other hand, depend on the motion of photo electron, which for the greater part of its pa is outside the atomic kernel; but which enters t kernel, and approaches very close to the nucleu this last part of the orbit is of the greatest importan in determining the distance between the componer of the doublet, which depends on the screening s this position. Sommerfeld found for the L double from Nb (41) to U (92), $s=3{\cdot}5$; for the optical double of elements with large atomic numbers s varies abo the number 4, for all p terms; only with the fi elements of the first period is s equal to 2. T difference between the value 4 and Sommerfel value 3·5 for the L doublets may be due to the fa that in the latter an L electron has been remove which diminishes the screening. The paper direc attention to the difficulties involved in the explan tion of the doublet distances by the relativity theor both for X-rays and for light; and also to tho involved in the alternative magnetic explanation.

Sedimentary Analysis of Photographic Emu sions.—Mr. F. F. Renwick has devised a new meth of attacking some of the problems connected wi photographic emulsions that promises to give resul of great interest (Journal of the Royal Photograph Society, August). He has constructed a water ba with regulators so that its temperature falls ve slowly but with great regularity, 0·4° C. an hou The melted emulsion is thus brought to its setti point without appreciable interference from conve tion currents. The block of emulsion obtained about 15 cm. high, and slices are cut parallel wi its base from various parts of it for examination. is found that passing from the top layer downwar the particles of silver salt increase in size, the pe centage of silver salt increases, the proportion of silv iodide to the total silver haloid increases, the turbidi decreases, and the sensitiveness increases. The sens tiveness in one case of the emulsion being 65, t layers gave as results 16 at the top increasing to 110 the bottom. By putting a clear gelatin layer und the emulsion, the larger particles fall into it and a thus more completely separated than by the oth method, or the sedimentation may be repeated c any given layer if a more complete separation wanted. Seven photomicrographs are given t demonstrate the results.

Imperial Botanical Conference.

THIS conference, the first of its kind, was held at the Imperial College of Science and Technology, South Kensington, on July 7-16, under the presidency of Sir David Prain. It was attended by a large number of overseas and home botanists, and many interesting topics were discussed.

Plant Physiology.

In the Section of Plant Physiology, Dr. F. F. Blackman organised an extremely illuminating discussion on "The Physiology of Crop Yield." In the general introduction to this discussion he indicated the five chapters of modern scientific investigation which combine to illuminate the problem of crop yield. The first dealt with the experimental study of the factors and conditions affecting growth, and was illustrated by papers from Dr. F. G. Gregory on the study of plant growth with controlled artificial light, and from Prof. V. H. Blackman on the results of electro-culture experiments. The second chapter concerned the ontogeny of the crop and duration of the development sequence. It was pointed out that crop-yield covers a wide range of special cases, the desired crop being either the whole plant, its wood, fibre, or bark, or some special morphological part, such as the petals, stamens, fruit, or seed hairs. The desired part comes at the end of a long development sequence, and, for this aspect of crop yield, detailed studies are required of the normal sequence of development of each crop plant combined with an exploration of its plasticity under natural and artificial variations of environment. Other problems arise out of the varying duration of the development sequence in the individual crop plants. These were illustrated by Mr. W. L. Balls' account of his method for analysing the development of the cotton plant by collating records of the significant stages prior to the production of cotton. The next chapter dealt with the quantitative relations between the final yield and the various "factors" which affect the development of the crop plant. Several investigators, notably Mitscherlich, have tried to formulate a general law governing the relation between the plant yield and the magnitude or intensity of all outside factors, but Mr. G. E. Briggs showed the inadequacy of such formulæ.

The fourth phase of this symposium treated of the complexity of the plant's spatial environment, namely, the soil, and was illustrated by Mr. J. J. Maskell's account of critical pot-culture work at Rothamsted. Lastly, the influence of the weather on crop yield was considered, and the great difficulty of disentangling the effects of the various components of the weather was pointed out. Dr. R. A. Fisher showed that by the methods of statistical analysis significant relations between weather factors and yield can be computed where a sufficient mass of data is available. In the general discussion which followed the presentation of the main thesis, Mr. F. L. Engledow drew a comparison between a tillering plant, such as wheat, with a non-tillering plant, such as cotton, as regards development sequence and its effect upon crop yield. Dr. H. M. Leake directed attention to the enormous influence of rainfall upon plant growth in monsoon countries, owing to the elimination of temperature as a limiting factor.

Genetics.

In the Section of Genetics, Mr. F. L. Engledow opened a noteworthy discussion on "The Economic Possibilities of Plant Breeding," Mr. W. Bateson being in the chair. Mr. Engledow confined his attention chiefly to the possibilities of hybridisation in the English wheat crop. He pointed out that the economic possibilities of breeding are measured by the prospects of producing new forms which will give better financial returns than the old. Enhanced returns may accrue from higher yield, better quality, and a number of other amenities, many of which indirectly affect yield and quality, and all influence financial return. Quality improvements, such as those exhibited by the varieties Yeoman and Yeoman II., produced by Professor Biffen, have great promise. Improvement of yield is more difficult, as the average yield of wheat per acre is already higher in England than in any other country. The best policy is to try to identify the plant characters which mainly govern yielding capacity, and then by synthetic breeding to produce optimum combinations of these characters suitable for different localities. Among "other amenities" are the qualities of disease-resistance, non-lodging, early ripening, and winter hardiness, all of which are of great importance, and the attainment of which seems reasonably possible. Dr. R. N. Salaman dealt with similar problems in potatoes, Mr. M. A. Bailey dealt with cotton, and Mr. J. M. F. Drummond with oats and turnips. In the other session devoted to genetics, Prof. J. Percival opened a discussion on "The Value of Selection Work in the Improvement of Crop Plants," to which contributions were made by Prof. R. G. Stapledon, Dr. W. L. Balls, Mr. G. O. Searle, and Mr. G. N. Sands.

Plant Pathology and Mycology.

Much attention was paid at the Conference to problems in plant pathology and mycology. Dr. A. W. Borthwick opened a discussion of much interest on the "Relation of Forest Pathology to Silviculture," in which an appeal was made for closer co-operation between the practical cultivator and the pathologist, and for the latter to confirm his laboratory investigations by further research in the forest. Mr. W. E. Hiley stressed the importance of the non-parasitic agencies which frequently cause severe mortality in seedling trees and loss of increment during later stages of growth. He urged the need of a careful study of the particular edaphic and climatic requirements of the various species used for forestry purposes, indicating that in the absence of complete suitability the trees often die or grow slowly, and are more than usually susceptible to parasitic attack. Dr. J. W. Munro and Dr. Malcolm Wilson also contributed to this discussion. Another session in this Section was devoted to a discussion on "The Relation of Plant Pathology to Genetics." This was introduced by Mr. F. T. Brooks, who summarised recent achievements in breeding disease-resistant varieties of crop plants, and pointed out the limitations of this method of disease-control. He stressed the importance of co-operative effort between plant pathologists and geneticists. Prof. Groom dealt with "Fungal Attacks on Timber," indicating the enormous losses which occur, and urging the need for more intensive research upon the problems involved. There were also interesting discussions on "Bud-rot of Palms," "Mosaic Disease of Sugar-cane," and "Brown Bast Disease of Rubber Trees."

Systematic Botany and Geology.

In the Section of Systematic Botany and Ecology, Dr. A. W. Hill opened a discussion on "The Best Means of Promoting a Complete Botanical Survey of the Empire." The present position of the Botanical Survey of the Empire was reviewed, and attention

was directed to the most pressing needs of the moment. It was pointed out that in some regions, such as India, Malaya, and South Africa, great progress had been made in the systematic study of their floras, but that in others, such as East Africa and some of the West Indian islands, little had yet been done to explore the vegetation resources. In urging that further facilities should be afforded to British botanists to go out and explore the floras of our overseas dependencies, Dr. Hill stated that at present we were indebted chiefly to foreign botanists for a knowledge of the plants of some parts of the Empire. A strong appeal was made for temporary interchanges of posts between overseas and home botanists. The value of a detailed botanical survey was emphasised, especially from the point of view of the economic resources and possibilities of the Dominions, Colonies, and Protectorates.

Another important and closely allied subject dealt with at the conference was the consideration of the best means of promoting the study of natural vegetation of the Empire in its ecological aspect. This was introduced by Mr. A. G. Tansley. It was pointed out that the modern study of vegetation regards each kind of plant covering, be it forest, scrub, or grassland, as having a natural life, economy, and history of its own. If a given type of vegetation is sufficiently well adapted to the local climate and soil, not threatened by the invasion of plants better adapted to all the conditions, and undisturbed by man, it will maintain itself indefinitely. Many kinds of vegetation are, however, mere transition phases to other types, which gradually replace the former covering by the natural invasion of individuals of different species, as, for example, when new soil, such as the alluvium of a river, blown sand, or the like, is occupied first perhaps by grasses, then by shrubs, and finally by trees. Again when forest is felled or burned, or when grassland is burned or overgrazed, new plants, often resulting in a different type of vegetation, invade and settle in the area. The original vegetation may or may not ultimately return. All these phenomena of the development of vegetation are referred to as "succession."

Such facts have, of course, long been well known to practical foresters and stock-raisers, but their systematic investigation is a modern study, vigorously pushed forward, especially in the United States, and also in some of our own colonies and Dominions, especially in New Zealand and South Africa, and to some extent in India and Burma. The results have proved most valuable as a practical guide to the treatment of the land. Overgrazing, for example, may greatly lessen or even destroy the value of a cattle range, by crippling the vegetative powers of the dominant pasture plants, and thus letting in less valuable or worthless herbs, "throwing back the succession" to an earlier stage. The range then has to be allowed time to recover by the natural succession of the grasses and other pastu plants which originally occupied it. A carefull regulated system of grazing or burning will maintai the most useful phase of the succession. The fir step towards the discovery of the most scientif and therefore the most economical and productiv treatment is the careful and thorough study, b trained investigators, of the natural compositio behaviour, and succession of the vegetation. Th has been amply proved, to mention but two example out of many, by the work of Sampson in the Unite States and of A. H. Cockayne in New Zealan The laws of behaviour of forests, on which alon can be based the most scientific treatment, are subjec to quite similar laws, and a marked feature of thi part of the Conference was the hearty support give by men with long practical experience of forestr work, such as Prof. Troup, of Oxford, who was fo many years a member of the Indian Forest Servic and by Mr. R. S. Hole, for some years botanist at th Forest Research Institute at Dehra Dun, to th proposals of the conference.

After very brief summaries of the present state o knowledge of the vegetation of the Crown Colonies an Protectorates, and of the Dominions, and a series o papers from representative men of experience o such work in different parts of the Empire, there wa a general discussion, concluding with resolution These aimed at the creation of a small central bod to superintend the preparation of a series of outlin monographs on the vegetation of the different part of the Empire. Though our knowledge is still, o course, very incomplete, it is of great importanc to collect and present what we do know in accessibl form, which will serve as a starting-point for furthe work. It is further proposed to arrange for th systematic record of future work uniform with th monographs. It is also proposed that the centra body, when formed, should at once put in hand th preparation of a pamphlet or small handbook co-operatively produced by the best availabl authorities in the Empire, dealing with the aims an best methods of field work in the study of differen kinds of vegetation, so that a practical guide may b available for new workers in this field throughout th Empire. The conference also adopted a resolutio that an adequate training for work on vegetatio should involve a practical training in systemati botany and ecology by competent teachers in th field.

At the closing session of the conference Prof. F. O Bower gave a striking address on the training o botanists, the possibility of effecting interchanges o staffs, and the need for further facilities for research which was followed by an animated discussion.

The conference terminated with a hearty vote o thanks to Sir David Prain for presiding over it labours. F. T. BROOKS.

The Maximum Recorded Temperature of the Air and its Circumstances.

IN the midst of the semi-desert plain of Jefara, between the coast of Tripolitania and the interior plateau, there exists an official Italian settlement situated about 25 miles south of Tripoli and 25 north of Gharian at some 300 feet above sea-level, known as Azizia. In 1913 Prof. Filippo Eredia, as a member of an agricultural commission, visited the locality, and wisely saw to the establishment of a meteorological station on the lines followed at many other points in the colony. He took great pains to ensure the accurate functioning of the instruments after approved methods, and has recently published the results for a period of seven, not, however, consecutive years: 1913, 1914, 1915, 1919, 1920, 1921, 1922. (Ministero delle Colonie. Sul Clima di Azizia (Tripolitania) Rome 1923.)

The mean yearly temperature for this period is 70·8° F. (21·6° C.), not an excessively high figure, but appropriate to the latitude well outside the northern tropic, the range being between 87·4° F. (30·8° C.) in July and 52·8° F. (11·6° C.) in January. Therefore, though the summer is torrid, there is a very decided cool season, slight frost being occasionally experienced with an absolute minimum for the period in question of 31·1° F. (−0·5° C.) in December. Maximum temperatures as high as 110° F. (43·3° C.), the figure

f each of the five months May to September, the a·olute maximum occurring with cloudless sky and SV. wind, on September 13, 1922, namely 136·4° F. (·0° C.), during a period of extremely high tempera- e throughout Tripolitania, even the coastal city o Tripoli recording as high as 113° F. (45·0° C.). Tis appears, and is so represented by Eredia, t be the highest authentic temperature of the air e r recorded on the globe, exceeding by 2·3° F. (3° C.) the previous "record" of 134·1° F. (56·7° C.) i Death Valley, in the south-eastern desert of Clifornia, on July 10, 1913, occurring, that is, in a s ilar, or rather higher latitude, close to the summer s stice, when the sun is nearly vertical. Records e eeding 115° F. (46° C.) are stated to be common in T politania, whilst other extremes from other regions, q oted for comparison, are 127·4 F. (53·0° C.) in the V rgla oasis of Algeria, on July 17, 1879, and 125·9 F. (·2° C.) at Jakobabad in N.W. India, on June 13, 1 97.

The remarkable circumstance connected with the A izia "record" is, we think, not so much the extra- t pical location, since it is towards the dry sub- t pical belts, where the days are longer, that the most i ense summer heats occur, but that the season of i occurrence there should have been equinoctial. Te mean temperature of the month of September for t e seven years in question is exceedingly high, s passing not only that of May, which is usual in n rthern extra-tropical latitudes, but also that of Jne, which is quite abnormal. This anomaly appears t be a local accentuation of the common Mediterranean c aracteristic of excessive summer heat lingering to a ater date than in higher latitudes, where the much g ater difference in the length of the day between s stice and equinox usually permits a rapid decline i temperature when August is over. Yet we know t t even in England there comes every few years, w h a drift northward of warm Mediterranean air, a surprising development, or resumption, of severe h t in September, with afternoon maxima at about 9 F. (32° C.), which sometimes causes the climato- l gical student to wonder how the oblique equinoctial s shine in this latitude has enough strength to raise the temperature to such levels. It should be remembered, however, that apart from the large reserve of heat stored in the air and the land- and sea-surface in autumn, and its easy transport by air currents from heated southern regions, enabling a smaller amount of solar radiation to raise the temperature to 80° or 90° F. (27° to 32° C.) than is necessary early in the summer, the very fact that the equinoctial sunshine is feebler, implying a smaller amount of surface heating, involves in turn, in conjunction with the relatively warm upper air in the autumn, a shallower vertical temperature gradient, and lessened tendency to convection, than at the high solstice. The result of this is that the heat is kept more to the surface, and that September "heat-waves," when they do occur, are liable to be scarcely less severe than those of July and August, and rather more so than those of May and June, when the fierce insolation, coupled with the yet cold upper air in early summer, favours instability with removal of the warm air from the surface and a checking of the afternoon maxima.

The circumstances attending the highest temperature which has yet been "caught" by our observing stations, may be summarised as follows: It occurred during a period of cloudless sky with light winds from the heated regions of the Sahara, in the middle of a semi-desert plain well inland from the sea, in a latitude (32½° N.) which, astronomically at least, belongs to the temperate zone, at a date (Sept. 13) only ten days on the summer side of the autumn equinox, when the sun is nearly half-way between its extreme solstitial position. The time of year is a prominent illustration of the general climatological principle that the seasonal extremes of temperature, even in continental regions, tend to lag well behind the corresponding extremes in the intensity and duration of sunlight. The latitude, too, illustrates the somewhat paradoxical principle that in general it is not the equatorial or hottest climates, that is, those with the highest mean temperatures, that furnish the occasional extremes of heat, say above 120° F. (*circ.* 50° C.), but the cooler and drier climates, near the confines of the tropics, which are intensely hot during the summer months.

L. C. W. BONACINA.

Past and Passing Peoples of Polynesia.

SOME important studies of two Polynesian peoples are published by the Bayard Dominick Expedition in the Memoirs of the Bishop Museum at Honolulu.[1] In vol. ix. Mr. H. D. Skinner gives a comprehensive account of the almost extinct Morioris of Chatham Islands. Of these only two living representatives were found in a population of foreigners, most of whom were Maoris. One other was living in New Zealand. In vol. viii. Mr. R. Linton discusses the material culture of the Marquesans, and in vol. ix. W. L. D. Sullivan their somatology. These are also a dying and diseased race and Mr. Sullivan doubts whether there is a wholly sound physical specimen save, while Mr. Linton considers that their language and portions of their culture may be preserved for several generations by their numerous half-Chinese or half-European descendants, who are more resistant to disease than the pure-blooded natives.

Mr. Linton's account of the Marquesans is restricted to their material culture, and other features having been dealt with elsewhere, only a short summary is given of social organisation and religion. But houses, canoes, stone artifacts, weapons and implements, clothing and ornament are described in detail and illustrated by forty-four full-page plates and eleven figures in the text. The few local differences in the islands are set out in a comparative table, which is repeated in greater detail to exhibit the relations of the Marquesan material culture to that of other Polynesian groups. Samoa and Tonga are found to have a closer cultural agreement than any other two localities. The Marquesas and New Zealand are almost equally close. The Society Island culture comes between the Samoan-Tongan and the Maori-Marquesan. Hawaiian culture resembles the Maori-Marquesan on the material side, but is more nearly related on the non-material side to the Society Islands and Western Polynesia.

The author gives the following hypothesis of the historic distribution of races and culture in the Pacific. The first arrivals in Central and South-east Polynesia were Negroid and Melanesian rather than Polynesian in culture. They settled in Tonga, Samoa, the Cook, Society, Austral, and Tuamotu groups. They did not reach the farther islands and came from Melanesia, probably Fiji. The next comers

were of the Caucasic race and came by way of Micronesia from Indonesia to Samoa. They produced a hybrid race and the south-east Polynesian type of culture. A fairly pure group of this Caucasic race reached the Marquesas and, mixed with the Negroids, arrived in Easter Island. Another group passed through Melanesia and modified the culture of the Eastern Melanesian Islands. The last comers were the Indonesians, who entered by way of Micronesia and thence passed to Tonga and, mixed with earlier people, to Hawaii. In Samoa they were resisted for a time by the earlier population, which in Niue survived into historic times. From Western Polynesia the Indonesians colonised New Zealand, spread over South-east Polynesia and reached the Marquesas. Later movements from the west have modified the culture and rendered it extremely complex.

In Mr. Sullivan's study of Marquesan, Samoan, and Tongan somatology, the distinctions of race are elaborated in a series of anthropometric tables based upon the examination of 84 adult men and 74 adult women of the Marquesan islands. These were compared with his similar studies of Samoans and Tongans in other papers. His estimate of the physical condition of the people has been already quoted. The measurements show the Marquesans to be "tall, with long, wide head, a high, wide face, and a high, wide nose. All of the dimensions of the head and body are large, indicating their massive size. They are on the verge of brachycephaly. But one cannot be sure that the heads are wholly undeformed."

According to Mr. Sullivan the "Polynesians" of the Marquesas, Samoa, and Tonga are a mixed people. He finds in them three racial types. In addition to the Polynesian population there is a second type resembling the Indonesian peoples of Malaysia, and a third extremely short-headed element. He has dealt mainly with the Polynesian and Indonesian types. The former are taller, with longer heads, higher faces, narrower noses, perhaps straighter hair, more beard and body hair, and lighter skin than the Indonesians. They appear thus to be the Caucasic people of Mr. Linton's hypothesis.

Mr. H. D. Skinner's monograph on the Morioris is exhaustive as regards the material culture of the people and their relation to the Maoris and other Pacific islanders. It is prefaced by an admirable summary account of the bodily and mental characteristics of the Morioris, their language, social organisation, and religion. This is derived partly from the very scattered accounts of earlier writers but has been considerably extended by Mr. Skinner's own investigations in the Chatham Islands. As in the Marquesan papers, the illustrations are an important feature. The paper before us contains thirty-six figures in the text, and thirty-five full-page plates.

With regard to the origin of the Moriori, Mr. Skinner gives a summary of their own traditions as recorded by Shand and the Maori version of Whatatoro, which was accepted as accurate by Mr. Percy Smith and Mr. Elsdon Best. The Moriori account seems to show at least two principal immigrations from unknown lands, the last of which took place, if the genealogies may be relied upon, about thirty generations ago, or about A.D. 1175. According to the Maori account they were a portion of the original inhabitants of New Zealand, called Maruiwi, who had been driven by a storm while fishing from a great land south-west of New Zealand. Mr. Skinner points out the inherent improbabilities of this story: the presence of women in a fishing party, the food required for a thousand-mile journey, and the impossibility of people in the cultural stage attributed to the Maruiwi possessing ocean-going canoes. The Maruiwi, moreover, were the physical antitheses of the Moriori. They were tall, thin, dark-skinned, with flat noses and straight hair, whilst the Moriori are short and bulky, brown-skinned, with prominent noses and hair often waved and sometimes frizzy. The Maruiwi lived wholly on forest produce, and knew nothing of fine weaving, but the Morioris had a traditional knowledge of cultivated plants, and made fine matting. Not one of the Moriori weapons described by Mr. Skinner is mentioned in the account of the Maruiwi.

Mr. Skinner's final remarks are important. The craniology of the Moriori shows close relationship with the Maori, and some social features are identical. The language is divergent, but Mr. Skinner suggests a likeness to the Kaitahu of South New Zealand. The evidence of material culture is decisively in favour of a Maori origin, though some evidence appears of a likeness with Easter Island and Melanesia in the conception of human and animal forms in art and in some hooks and adzes.

Taken as a whole these three studies considerably increase our knowledge of the Polynesians. But the conclusions have yet to be compared with the evidence of language, sociology, and religion.

SIDNEY H. RAY.

Ancient and Modern Arithmetic.

THE special object of the papers referred to below[1] appears to be to establish one main thesis, namely, that there was no such thing as arithmetic in our modern sense before the sixteenth century. To quote the author's words: "Modern arithmetic, which is a peculiarly Western invention, is yet barely 400 years old. Prior to 1500, and during some 3500 years of unbroken mathematical continuity and evolution, the science and art of calculation differed absolutely from anything in vogue with us."

The sole direct argument by which the author supports this thesis is the occurrence, in two particular treatises on arithmetic which he quotes, of a method of multiplying two digits to which he applies the general term "calculation by deficients." The anonymous English author of "An introduction for to lerne to recken with the pen, or with the counter, accordying to the trewe cast of algorism, in hole numbers or in broken, etc," written in 1546, multiplies 7 by 5, and for this purpose substitutes $(10-3)$ for 7, arriving at the result by a process which is equivalent to $7\times5=(10-3)\ 5=50-15=35$. The Frenchman Oronce Fine (not "Finé"), whose work was first published during the years 1530–32 (not 1525), uses an even more roundabout process equivalent to $7\times5=(10-3)\ (10-5)=15+(7-5)\ 10$ [or $(5-3)\ 10$] $=15+20=35$.

Now this "complementary" method of multiplication (as it has been called) is a familiar item in most histories of mathematics: there is nothing new in Prof. Brockwell's discovery. He says, indeed, that the anonymous English treatise "appears to have been entirely overlooked by all the more recent writers on the history of mathematics both in Europe and America"; but, if he had referred to David Eugene Smith's "Rara Arithmetica" (1908) he would have found (p. 244) a notice of this anonymous work and of the later edition of it published in

[1] "The Transition from Ancient to Modern Arithmetic, I. II." (reprinted from *The Teachers' Magazine*, Montreal, Dec. 1923 and April 1924); "Calculation by Deficients (a remarkable aspect of the Evolution of Arithmetic)," a paper read before the American Oriental Society, April 23, 1924; by the Rev. C. A. Brodie Brockwell.

574. He would also have found in the same "Rara Arithmetica" (p. 76) a case of "complementary" multiplication from an earlier treatise (Huswirth, 1501). But the strange thing is that our author seems to infer from these cases that before 1546 such multiplications were never done in any other way, that "none of our tables of arithmetic had been invented as recently as 1500 A.D.," that our multiplication-table had not been invented," and that, "while men could multiply, as we do, up to five times five by the fifteenth century, they could not go beyond this." There is, indeed, no trace of multiplication-tables in Egyptian records, but the Babylonians had not only multiplication-tables but also tables of divisions, of squares, of square roots and cube roots. The Greeks and Romans certainly had multiplication-tables: there is one in Nicomachus about A.D. 100) and in Boëtius (about A.D. 500), and they must have been used much earlier. There are also multiplication-tables in a treatise on abacus-reckoning by Bernelinus (about A.D. 1020), in the "Liber abaci" (1202) of Leonardo of Pisa, and in Widman's Arithmetic (1489). So much for the multiplication-table. (The fact that Pepys had such trouble in learning the multiplication-table is of course no proof that schoolboys and others had then (1662) only just begun to use it, and that it was then little more than 100 years old; other great men have been without a gift for arithmetic.)

The story of the arithmetical operations is similar. Eutocius (5th century A.D.), in his commentary on Archimedes, gives various long multiplications differing from ours only in the arithmetical notation used. Theon of Alexandria (4th century A.D.) divides 3515° 20′ 15″ by 25° 12′ 10″ and extracts the square root of 4500° in degrees and sexagesimal fractions by a procedure which, allowing for the difference of notation, is the same as ours. Long multiplications in the Treviso Arithmetic (1478) are done in a way exactly equivalent to our method, and in some cases they are written out in exactly the same form. So with long divisions, which appear, in the same form as with us, in an Italian MS. of about 1460 (see D. E. Smith, *op. cit.* p. 462), and in printed works by Calandri (1491) and Luca Paciuolo (1494). It is true that some ancient systems of numerical nomenclature expressed certain numbers on a subtractive principle: cf. the Roman *undeviginti* and *duodeviginti* for 19, 18, etc., and the numeral signs iv., cxc., etc. The Babylonians, too, used the same principle commonly, if not so systematically: *e.g.* we find 118 written as 120 *minus* 2, and 27 as 30 *minus* 3. Possibly the 'complementary' multiplication owes its origin to this feature of the Roman numeral system. But there seems to be no trace in India, Arabia, Egypt or Greece of the "complementary" method of multiplication.

Such being the facts, few, we imagine, will agree that arithmetic was dominated continuously from the earliest times to the sixteenth century by "calculation by deficients," and that our modern arithmetic was a Minerva-like offspring of that century.

Prof. Brockwell finds indirect evidence for his theory in a multitude of allusions in literature which hint at odd systems of numeration and curious processes of calculation. He draws mostly from Hebrew and Biblical sources and states a number of interesting puzzles, *e.g.* "Why from time immemorial had *aleph*, the first letter of the Hebrew and Phœnician alphabet, the index both of 1000 and of 1?" "Why, when speaking of the seven days of the first creation story, did the mediæval Hebrew exegetes describe them as seven thousand days?", and so on. These puzzles may no doubt offer a considerable field for further research into primitive arithmetic.

We may observe incidentally that our author assigns Philolaus to the 5th century A.D. (instead of B.C.), making Isidorus, Bishop of Seville (A.D. 560–636), "a little over a century later." He also speaks of Proclus, the Neo-Platonist, as "the Egyptian mathematician"!

University and Educational Intelligence.

Liverpool.—Applications are invited for the Derby chair of anatomy, the duties of which post will begin on January 1 next. The latest date for the receipt of applications by the registrar is October 1.

A demonstrator is required in the department of mathematics of the City and Guilds (Engineering) College, South Kensington. The latest date for the receipt of applications and statement of qualifications, by Assist. Prof. Klugh, at the College, is August 30.

Applications are invited for two research assistantships in the Physical Laboratory of the University of Toronto. Candidates must be university graduates with special training in physics. Applications should be sent to Prof. J. C. McLennan at the University.

Applications are invited for the professorship of surgery in the University of Otago, New Zealand. Particulars of the appointment and a form of application may be obtained upon written request to the High Commissioner for New Zealand, 415 Strand, W.C.2. The completed form must be returned by August 31.

As part of the Vacation Course for Teachers arranged by the West Riding Education Committee at Bingley, Mr. Wilfred Mark Webb, general secretary of the Selborne Society, gave a lecture and demonstration on August 12 dealing with "The Cinematograph in Education." He considered two aspects of the subject, namely, the use of moving pictures in the ordinary curriculum in connexion with the definite teaching of various subjects in which it is recognised that they may be helpful, and during out-of-school hours for broadening the pupils' outlook. He strongly emphasised the need at present of superseding the lantern slide only when it is advisable to represent movements which are going on, or can be introduced as an improvement upon the still picture, and even upon the blackboard, in the building up of drawings, diagrams, or maps, or by making models work upon the screen.

In continuation of the policy of training aircraft apprentices in the skilled trades of the Royal Air Force, two examinations for the entry in January next of more than 500 boys, between the ages of 15 and 16½ at the time of entry, will be held on October 17 and November 4 respectively. The closing date for the receipt of completed forms of application for the first examination, which is an "open" competition conducted by the Civil Service Commissioners, is August 28, and for the second "limited" competition, which is carried out by the Air Ministry in conjunction with the local education authorities, the forms of nomination must be received in the Air Ministry by October 7. For the former, forms of application can be obtained from the Secretary, Civil Service Commission, Burlington Gardens, London, W.1. For the latter, nominations can be obtained through headmasters of schools, Advisory Committees for Juvenile Employment, the Boy Scout Association, and officers commanding Territorial Cadets.

A "FEDERALISATION" of the London Institute of Historical Research in the interests of students in all British universities has for some years past been advocated by Sir Richard Lodge, and he was able to announce at the universities' conference of May 10 that the idea had been adopted by the Council of the Institute. In America a movement of a similar character has been set on foot with the object of utilising in the future more fully than in the past the material and scholarly resources at Washington for purposes of graduate study and research by students from all parts of the United States. The attitude of the leaders of the movement is summed up in a phrase used by Prof. Leuschner of California in a paper presented last November to the Association of American Universities: "Every graduate school should extend to Washington." Prof. Leuschner went on to say that American graduate students move about more and more freely and that this development is not merely due to the advice of deans and professors but is increasingly due also to the scholarly initiative of the students themselves. He admitted that this freedom is "impeded at times by a certain *local pride or provincialism of departments* and their representatives, who fear loss of students and of prestige by carrying it to its logical conclusion." He stated, however, that it is fully recognised that few universities can undertake distinguished work in many branches. On the important question whether fellowships are allowed to operate as impediments to free migration, he went no further than to say that he hoped no fellowships are being maintained that are not primarily established for the fullest enjoyment of great opportunities in the field of scholarship and research.

THE report of the Imperial Education Conference Committee on the use of the cinematograph in education has been issued recently (H.M. Stationery Office, 1924. 1s. net). Not the least part of the value of the report lies in the extracts from memoranda submitted by inspectors and secretaries of education who have watched experiments, by headmasters who have introduced films into their schools, and by teachers who have actually used the cinematograph in teaching. The positive conclusions reached are those which are fairly obvious: namely, that the cinematograph can be of real value as an adjunct to present methods, and that it should be recognised as part of the normal equipment of educational institutions, especially for use in teaching nature study, geography, science, and industrial processes. It is noteworthy that those who have had practical teaching experience with the instrument are much more enthusiastic than are others. Though nothing is said in the report, opinion seems to be swinging round to the view that the classroom rather than the picture theatre is the place for educational work with the film. Importance is rightly attached to the fact that projectors and screens now exist quite suitable for use in a classroom, and that the technical difficulties which used to prevent their use have disappeared, though the difficulty of cost remains. The absence of suitable films is, however, referred to again and again. One hint is given, that films should not take longer than ten minutes to run through; the writers of this note would say five; but this does not carry us very far. The crux of the problem is reached when the Committee says that the films "which are procurable are unco-ordinated and do not fit in with one another or with the ordinary school syllabuses." It is the well-thought-out teaching syllabus which dominates the situation, and film producers who desire to get the patronage of, or to help, teachers must take account of it.

Early Science at the Royal Society.

August 26, 1663. It being related by Mr. Oldenburg the secretary, that he had been desired by Monsieur Ludolf, councillor of the duke of Saxe-Gotha, to procure from the society, for a domestic of that prince who was to be sent into Egypt and Ethiopia, some instructions of inquiries fit to be made in those parts; the society desired Mr. Boyle, Mr. Henshaw, and other members to draw up some queries for that purpose. [Among these was one, "Whether, tho' the plague be never so great before, yet on the first day of the river's increase, the plague not only decreaseth, but absolutely ceaseth; not one dying of it after?"]

August 27, 1662. Upon the occasion of the manuscript philosophical books, which were presented to the society for their examination, and received a good character from those members, who had read them, it was ordered, that no books presented to the censure of the society shall receive approbation from them; but only, if the society think fit to refer such books to one or more of the fellows, esteemed by them competent judges thereof, that the report made thereof to the society by such fellows, may be communicated to the authors of the books thus presented; and that it may be signed by one of the secretaries.

August 28, 1661. Dr. Clarke read a paper entituled "Observations on the humble and sensible plants in Mr. Chiffin's garden in St. James's Park, made August 9, 1661."—Mr. Boyle presented the book which he had published since the order was made, that every member, who should publish any book, should give one to the society's library.

August 29, 1662. In the afternoon of this day the president and council, with other members of the society, waited on the king, to return him the thanks of the society for the patent of their establishment. The president made a speech to his majesty [This extols the king's grace and favour, and expresses "our firm resolution to pursue sincerely and unanimously the end—the advancement of the knowledge of natural things, and all useful arts, by experiments."]

1678. His grace the Duke of Norfolk being present at this meeting, renewed the declaration of his gift to the Society of the Arundelian library; and gave his consent and direction for the removal thereof: and that they should have liberty to exchange such books thereof, as were duplicates, or which they should think not so proper for their use, for others of equal value. His grace added, that Sir William Dugdale had presented him with a catalogue of books of heraldry, as he in the name of the heralds had desired. But upon perusal of the same finding many of them to be such, as did not so properly belong to the business of heraldry, the duke was desirous, that Sir Robert Redding and Mr. Evelyn would peruse the said catalogue, and consider what were most proper for the college of heralds, and what might be more proper for the use of the Society, and to moderate and adjudge the matter between the Society and college. But it was his grace's further pleasure and desire, that in case the Society should be dissolved (which it was his desire and hope they never would be) the said library might revert to his heirs. The Society by the mouth of the president returned his grace their most humble and hearty thanks for this his truly noble present: and ordered Mr. Hooke to take care, that the determination of the matter between them and the college of heralds might be made with all convenient speed; and that thereupon the books should be forthwith removed to Gresham College.—Mr. Henshaw moved, that a fair catalogue of them might be made, to be delivered to the duke to remain in his grace's custody.

Societies and Academies.

PARIS.

Academy of Sciences, July 21.—M. Guillaume Bourdan in the chair.—A. **Lacroix**: The grained motive rocks of the archipelago of Kerguelen. Complete analyses of twelve rocks collected by M. E. Peau; including nepheline syenites, phonolite, quartziferous syenites, biotite granite, trachyte, and basalt. These rocks suggest the existence of much older volcanic formation than the lava constituting the main formation of the archipelago.—Paul **Appell**: The movement of a heterogeneous fluid mass, subjected to the mutual attraction of its particles, round the centre of gravity.—A. **Haller** and (Mme.) P. Bagnart: The preparation of the monoalkylpulegones.—Ch. **Moureu**, A. **Lepape**, and H. **Moureu**: The radioactivity of some thermal springs of Madagascar (the Antsirabe basin) and of Reunion. Determinations of the radium emanation in the gases from seventeen springs in Madagascar and eight in Reunion have been made. Minute amounts of thorium emanation were detected in one spring only.—Gabriel **Bertrand** and Hirosi **Nakamura**: The comparative physiological importance of iron and zinc. Experiments on young mice show that a deficiency of zinc in the food produces a more marked effect on growth than a deficiency of iron.—Charles **Rabut**: The rounding of dams and chimneys.—E. **Mathias**: The terminal forms of flashes of lightning.—M. de **Séguier**: The isomorphisms of certain groups.—Emile **Jouguet** and Maurice **Roy**: The paradox of d'Alembert in the case of compressible fluids.—J. **Guillaume**: Observations of the sun made at the Lyons Observatory, during the fourth quarter of 1923. Observations were made on 56 days, and the results are given in three tables showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—R. **Jarry-Desloges**: Contribution to the study of the disaggregation of the southern polar-cap of the planet Mars.—Charles **Platrier**: Contribution to the study of various physical phenomena by transformation of linear differential equations into integral equations.—L. **Dunoyer** and P. **Toulon**: A remarkable property of the positive column of the mercury arc. Action by the influence of external baths.—L. **Vegard**: The luminescence of solidified gases and their application to cosmic problems.—G. **Bruhat** and M. **Pauthenier**: The absorption of ultra-violet rays by carbon bisulphide.—J. **Errera**: The solid state looked at from the electric point of view; dispersion in the Hertzian domain.—J. **Escher-Desrivières**: Polonium carried down by silver chloride. A quantitative study of the removal of polonium from solutions by precipitation of silver chloride, the solution containing variable amounts of hydrochloric acid, sodium chloride, and potassium chloride.—J. H. **Le Bel**: Small variations in the heat dengaged by various specimens of radium bromide. A specimen of radium bromide, placed in a Dewar tube in a cellar 20 metres below ground, gave a perfectly steady temperature rise, which, however, once or twice a month, showed a slight fall. A second apparatus, placed under the same conditions, indicated the same minima at exactly the same times. The phenomenon appears to have its origin outside the radium, and it would be desirable to repeat the experiment elsewhere, preferably in America.—James F. **Brennen**: The carrying down of polonium by colloids. The colloid is precipitated by an electrolyte, and the amount of polonium in the precipitate determined. It depends on two factors; the time that the polonium has been in contact with the colloid before precipitation and the time that the precipitate has been allowed to stand before filtration. Colloidal silver or ferric hydroxide retains practically all the polonium (97 to 98 per cent.).—D. **Yovanovitch**: An apparatus for measuring the heat disengaged by radioactive bodies.—Jean **Thibaud**: The γ-rays of very great quantum and the photo-electric origin of the natural β spectrum of radium.—André **Job** and Guy **Emschwiller**: The photochemical limit and the energies of linkages.—H. **Gault** and F. A. **Hessel**: The pyrogenic dissociation of hexadecane. The apparatus used has been described in detail in an earlier communication. Analyses of the gas and liquid produced are given for seven temperatures varying between 390° C. and 815° C.—P. **Langlais** and J. **Goby**: Contribution to the study of essence of iris. In addition to the constituents already known, the presence of six saturated fatty acids has been proved, caprylic, pelargonic, capric, undecylic, lauric, and tridecylic acids.—Marcel **Delépine**: The transformations of the pinenes by acids.—Max and Michel **Polonovski**: The degradation of the hydrogenated derivatives of eserine.—**Pastureau** and H. **Bernard**: Ethyl-trimethyl glycerol.—Alphonse **Mailhe**: The decomposition of animal wax. A study of the destructive decomposition of beeswax in the presence of catalysts.—Pierre **Viennot**: The boring of Abatilles, near Arachon.—Emile **Belot**: The application of the principles of the dualist cosmogony and of isostasy to the study of various geological problems.—J. **Cabannes**: The transparency of the atmosphere.—J. **Liouville**: The corals harmful to the trawlers of Morocco.—Mlle. Y. **Ménager**: The use of sodium chloride as a standard in analyses of sea-water.—René **Souèges**: The embryogeny of the Typhaceæ. The development of the embryo in *Sparganium simplex*.—Mme. Paul **Lemoine**: The distribution of the calcareous algæ (Corallinaceæ) according to depth in the Mediterranean.—André **Mayer** and L. **Plantefol**: The water exchanges of mosses with the atmosphere.—André **Charriou**: The absorption of potash by humic acid.—F. **Heim** and R. **Audubert**: The agglutinating power and coagulating power of coagulation agents towards rubber latex.—Ladislas **Smolik**: The influence of electrolytes on the total surface of the elements of the soil.—R. **Fosse**, Ph. **Hagene**, and R. **Dubois**: The gravimetric estimation of cyanamide as xanthyl-urea.—Jules **Amar**: The preservation of living tissues. The solution proposed contains sodium phosphate, 3·0, sodium bicarbonate, 3·0, and sodium chloride, 2·0 in water 1000. Advantages are claimed for this solution over the solutions of Locke, Ringer, and Biedermann.—Auguste **Lumière** and Henri **Couturier**: The toxicity of normal sera.—L. **Mercier**: *Geomyza sabulosa*, a microdiptera with reduced wings; loss of the faculty of flight in this species as a result of the drosophilian process.—G. **Athanassopoulos**: The geographical distribution of fresh-water fishes in Greece.—Mlle. **Kostritsky**, Mme. **Toumanoff**, and S. **Metalnikow**: *Bacterium tumifaciens* in the grub of *Galleria mellonella*.—M. **Weinberg** and A. R. **Prévot**: The use of anatoxins for the preparation of antigangrene sera.— — **Paillot**: The etiology and epidemiology of *grasserie* (a disease of the silkworm).—Mme. Jean **François-Péry**: The influence of sunlight on the development of a soil protozoa, *Colpoda cucullus*.

SYDNEY.

Royal Society of New South Wales, May 7.—R. H. **Cambage**: Presidential Address, Australian resources of liquid fuels. Mr. Cambage expressed the opinion that it is imperative the most intense research should be undertaken to devise, on commercial lines, some method of treatment of coal by which a very much higher percentage of liquid fuel may be extracted or manufactured from this commodity than is obtained by present-day methods in connexion with coking, or that some other process, such as that of com-

bustion of finely divided particles, may be perfected, by which the power may be obtained direct from coal without converting it into oil.

June 4.—Dr. C. Anderson, president, in the chair.—C. **Hedley**: Differential elevation near Sydney. Two raised terraces of marine erosion situated on the ocean side of North Head are described. The highest is elevated about thirty feet. This pair of raised beaches again appears three miles to the westward. But there the highest is only about eight feet instead of thirty above the present level of erosion. The conclusion is drawn that this differential movement is the result of a fold or earth wave at least six miles wide and thirty feet high.—W. G. **Woolnough** and J. L. **Somerville**: A contribution to the geology of the Irwin River Valley of Western Australia. Two strongly unconformable Pre-Cambrian formations are distinguished. The well-developed Permo-Carboniferous system is zonally subdivided chiefly on a lithological basis. The glaciology is described in some detail. Reasons are advanced for regarding as Cainozoic (Plateau Beds) much of the formation previously described as Jurassic. Well-marked step-faulting towards the Indian Ocean is indicated. The probability of the existence of economically important deposits of coal and salt is considered remote.

Linnean Society of New South Wales, May 28.—E. C. **Chisholm**: Eucalypts of the Blue Mountains and their defined areas. Thirty-four species of Eucalypts have been observed by the author on the Blue Mountains and the distribution of those species in this region is recorded.—J. R. **Malloch**: Notes on Australian Diptera. No. ii. Notes on a number of species in the subfamilies Anthomyiinæ, Phaoniinæ, and Fanniinæ. Nine species are described as new, and a key is given to the three Australian species of Hylemyia.—R. **Veitch** and W. **Greenwood**: The food-plants or hosts of some Fijian insects. Part 2.—T. **Steel**: Observations on *Helix aspera* in Australia. This shell is usually considerably smaller and always lighter in weight in various parts of Australia and in New Zealand than is normally the case in Europe. It is identified with the var. *tenuior* Shuttl. Other varieties found near Sydney are vars. *depressa* Paul and *puncilulata* Bandon. A specimen distinctly approaching the cornute form was also found, but no sinistral examples have been met with. Marked diminution in size of the shell in the adult, following prolonged, dry, hot conditions, is noted.

June 25.—Mr. R. H. Cambage, president, in the chair.—W. Docters **van Leeuwen** and H. H. **Karny**: Two new thrips-galls and their inhabitants from New South Wales. Descriptions of the occurrence of *Euoplothrips bagnalli* on *Randia chartacea*, and of *Cryptothrips* (?) *intorquens* and *Euoplothrips bagnalli* on *Smilax australis*.—A. M. **Lea**: On some Australian Scarabæidæ. The paper deals with cockchafer beetles; notes on various species are given, and thirty-eight species, mostly of the subfamily Melolonthides, are described as new.—C. **Iredale**: Results of Roy Bell's Molluscan Collections. The collection here studied is only one of half a dozen made at important zoological points on and about the Australian coast for the purpose of elucidating geographical problems. The Twofold Bay Mollusca agree in species and genera with those from Sydney, but entirely lack a northern Australian element, and show a small percentage of southern Australian forms, a number of additions of such species being made to the N.S.W. fauna. A few new species were secured, while the fine series, in perfect condition, of many species have already furnished important results, such as the viviparous nature of some Turritellid molluscs and the polyphyletic nature of the Minolioid group of Trochoids. A most important feature of a few dredgings made in 50-70 fathoms is the g resemblance between the molluscan fauna at pre living at that depth and the fossils of the Upper of the Muddy Creek deposits.

VIENNA.

Academy of Sciences, June 12.—L. **Lämmerm** On the dispersal of warmth-loving plants in the district. Researches on the light- and climate-rela of the stone pine.—F. **Ris**: Odonata, describin species, two from the White Nile previously undescr —H. **Spandl**: Freshwater Amphipodes including t of the Caspian Sea and of Lake Baikal and of terranean waters, and a discussion of the migrati marine Amphipodes into fresh water.—V. **Brehm**: Entomostraca from the Handel-Mazzetti exped to China.—E. **Dittler** and A. **Kohler**: Experim researches on disentangling potassium-sodium fels Reactions of this sort have been recognised for K NaCl, but so far little has been done on the silic Diffusion in the solid condition can be shown to place in thin sections. Perthite was heated i electric resistance furnace for 500 or more hours temperature of about 1000°. After heating, the d ence in the refraction of the two components of per had completely vanished. The capacity of albite orthoclase to diffuse into each other at high tem tures, and whilst still solid, is favoured by the cir stance that these felspars can form mixed crystal

June 20.—**Kerner-Marilaun**: Solar-climatic peratures in palæozoic antiquity.—H. **Handel-M zetti**: Plantæ novæ Sinenses. The China Indemnity Bill.

CHINA is perennially a land of contrasts. This holds not merely in material things that strike the eye—such as nodding the head to say no, shaking it to say yes; putting on the roof of a house before laying its foundation; ending the book on the page where ours begins—but in spiritual things also, such as being content with an ethical system rather than a religion, but making its practice an inalienable part of the inner man. Nor does the spirit of contrast end here. It affects, to his surprise, the foreigner, and in particular the Englishman, who lives and works in China. Day by day in business matters he is inconvenienced by Chinese unpunctuality, by their waste of time, their avoidance of definite statement, their shrinking from responsibility, their superstitions; but when challenged as to the outcome of it all, he acknowledges, as recently a Consul-General did at a social gathering, that though he is at times annoyed or angry with them, yet when he thinks of the Chinese, he remembers mainly their honesty, their habitual courtesy, their good humour, so that liking and even affection becomes his ultimate attitude.

Another aspect of this spirit is presented by the *Times* of August 9, which includes both an article from a correspondent entitled "A Way to help China" and a leader on "Chinese Problems." The latter, while indicating how important to British trade would be even a slight improvement in China's present political conditions, supports the views expressed by its correspondent as to the value of co-operation, and declares "the line of action he proposes will lead to success. Others will mean confusion and failure." The contrast seen here amounts to this, that while our contemporary, by means of letters from its well-informed correspondent in Peking, has continuously pointed out the increasing antagonism, amounting even to danger to life, which foreigners at present experience in China, the article in question, which advocates as its one aim the cultivation of Anglo-Chinese friendship, is commended as being "an admirable and directly practical way of making British influence felt in China in its most fruitful form."

We now turn to the way there proposed for helping China: to devote to education practically the whole—or say nine-tenths—of the British quota of the Boxer Indemnity Fund, amounting to 400,000*l.* a year and payable until 1945. The article first directs attention to certain defects in the China Indemnity Bill, which in the House of Commons has passed its second reading and the report stage: its purposes are as yet indefinite, but an amendment, tabled in fact by members drawn from all three political parties, proposes that these

purposes, like those adopted by Japan and the United States in the same matter of indemnity remission, shall be defined as "educational or cultural." This amendment will probably be adopted, for Great Britain, pressed by both the United States and Japan in the Chinese markets, cannot afford to take a lower line, even in name, than they. In that case, the Advisory Committee which the Bill proposes to set up to advise the Foreign Secretary will have to be constituted accordingly, and should contain not only persons having knowledge and experience of educational and medical work, but also, in view of the great and increasing importance of female education, a Chinese woman, who, like her compatriot proposed to be included on the Committee, should favourably impress Chinese opinion by appropriate scholarship and educational experience.

To us, the article is of particular interest, because it boldly states that there is only one way to help China permanently and radically: that is, by education, and, moreover, an education which includes science. This assumes that no ground more favourable than education exists for the promotion and exercise of friendly relations between British and Chinese. The field includes, of course, such institutions and activities as universities, colleges and medical schools, and the promotion of scientific research in them and in related institutions. If the right method be adopted, it will be possible to bring home to the Chinese, who are both a shrewd and a responsive people, the value to China of including in the curriculum of higher education, as well as the study of science, that of letters, and of making it possible for Chinese youth to acquire some of the characteristics which mark the traditions of Public School education in England at its best—its spirit of initiative, of independence of character, of the desire for corporate well-being and voluntary service.

As there is only one way of radically helping China, so there is only one method of making this help permanent. The method is that of co-operation. This should be full and continuous, alike in formulating any general plan and in carrying it out in detail. To ensure that co-operation should be of this kind, at once real, and personal, and officially recognised, an indispensable condition is that an admixture of Chinese and British members should be an element in the constitution of the Foreign Office Advisory Committee, the local Committees in China, and the Boards of Management of all aided institutions, whether under Chinese or British management. This principle has been initiated and commended by the foresight of the Foreign Office in arranging for the inclusion on the Advisory Committee of "at least one citizen of the Republic of China." It remains to extend the p ciple and to apply it comprehensively. Local Educa Committees, which would act under such general r lations as the Advisory Committee will draw up, m be formed in each of China's eighteen Provin capitals, the Chinese and the British Chambers Commerce there each nominating one-third of members, the remaining third being partly *ex o* and partly co-opted or nominated. In the of Provinces not having a British Chamber Commerce, it would not be difficult, by nomina or co-optation, to provide the necessary third, s not more than four members at most would required. A similar method might be employe providing the admixture of representatives Boards of Management of higher educational ins tions, wherever situated.

The Advisory Committee as the central autho would itself deal with central institutions such as uni sities, and with central activities such as medical w scholarships, and Chinese students. As to t activities, it may be noted: that the Anglo-Chi community, in all their representations to the Br Government, have emphasised the high value British medical work, of which they are rightly pr that scholarships stand for the Chinese tradition which learning opens the way to distinction ar career; and that Chinese expenditure on stude which would involve a Chinese Institute in Lon and a subsidised hostel, would tend, by means mutual international intercourse and understand partly to open the world to China and partly to China to the world.

If some Anglo-Chinese critic should object that Chinese are not ripe for this equal hand of fellows the answer must be: first, that nothing is so uplif as this gesture, provided it be continued long enc to show that it is real; and next, that not even keenest detractor of China will deny the pervasive among her people of the characteristic of respons ness. In this the Chinese are faithful to the teach of their great sage, who, when Lao-Tzū challenged great maxim, "Return good for evil," by ask "With what then will you recompense kindness replied, "Recompense injury with justice, and rec pense kindness with kindness."

This then is the way to help China: by cultivat on both sides, the power to forget past injury; enabling each nation to realise, through real comprehensive co-operation in education, the characteristics of the other; and by both f accepting the truth that education, while it always a venture of faith, holds, as no other m ment does or can, the promise of the future.

Probability in Theory and Practice.

surances sur la vie: calcul des primes. Par Henri Galbrun. (*Traité du calcul des probabilités et de ses applications,* par Émile Borel. Tome 3: *Les Applications de la théorie des probabilités aux sciences économiques et biologiques,* fascicule 1.) Pp. vi+311. (Paris: Gauthier-Villars et Cie, 1924.) 35 francs.

ments de la théorie des probabilités. (Cours de la Faculté des Sciences de Paris.) Par Prof. Émile Borel. 3e édition revue et augmentée. Pp. vii+226. (Paris: J. Hermann, 1924.) 18 francs.

THE treatment of the subject of probability has developed in recent years mainly in its application to statistical research, and a large amount of work has been produced in attempts to express frequency distributions or correlation surfaces in mathematical forms or in measuring correlations and periodicity. In all these researches a practical object was to be attained, and there is almost unlimited scope for further development, but there still remain two classes of books on probability, which are exemplified by Prof. Borel's "Elements" and Dr. Galbrun's actuarial text-book, which are but slightly connected with modern statistical work.

Prof. Borel's book is an excellent example of the treatment of probability which begins with games of chance and drawings from urns; it leads, through the approximations to factorials, to the normal curve of error. Prof. Borel discusses geometrical problems, shows the Gaussian treatment of errors of observation, gives Bayes's theorem, and then indicates the promised land of statistical investigation and tells us of some of the many fascinating places we may find there. But he leaves us, as it were, at Mount Horeb. The book is already known in its earlier editions as a good text-book on the subject within the limits indicated, but it ends at the point where many modern readers begin to be most interested.

Dr. Galbrun's subject, in some respects, begins after the interest of most readers has expired, for actuaries are bound to assume that they know the probabilities of death in order to make their calculations, and modern work has been mainly concerned in finding ways of interpreting the statistics on which the probabilities are based. Unlike the well-known English text-book writers, however, Dr. Galbrun attempts to bridge this gap, as he discusses the "errors" involved in some of the probabilities, endowments, and annuities with which he deals, and it is this part of his work that calls for special comment. In statistical work it is customary when calculating a coefficient of correlation, or a mean, or some other function, to set out after the result the probable error of the figure reached as some indication of the deviations that will arise in such cases, and the natural course would appear to be to adopt some such method in dealing with the values that an actuary requires. The matter is, however, more complicated than that of the means to which we have referred. There are not only the deviations that arise in the original statistics, but also, even if the true probabilities of death in the future were known, there would be deviations from these probabilities just as there are deviations from the probability of a head falling in a coin-tossing experiment where the probability is known. Dr. Galbrun does not attempt to give the probable errors of various actuarial functions, but makes estimates of what we may call a "safety margin" which will cover 99 per cent. of the cases. This margin could, in theory, be used as a loading to the premiums charged, but if it were used for small classes of business it might, by increasing the premiums, reduce the amount of business and so render the loading insufficient on the theory adopted. Any such loading must, in practice, be regarded somewhat broad-mindedly, and Dr. Galbrun has not striven after extreme accuracy but has used rather rough approximations.

We may now turn for a moment to some other points in the work. In many ways it follows familiar lines, with an unfamiliar notation, and the methods of working out the values of annuities, assurances, and premiums require little comment. We are a little surprised, however, to find that in the evaluation of certain complicated benefits, Lubbock's formula is used, so that a number of differences have to be calculated and the arithmetic becomes troublesome. The customary method in Great Britain of using Simpson's or some similar rule seems preferable. In a few cases, also, Dr. Galbrun spoils his effect a little by using an approximation when an accurate result presents no real difficulty, and we would willingly have given up some of the work on survivorship annuities for a concise treatment of apportionable annuities.

The book concludes with an appendix of thirty pages discussing mathematically the application of the law of error to the probabilities of death, and in this connexion we would throw out a word of warning. The probability of dying in a year at the ages that are most important in practice are small (they are less than 0·02 at ages under 55), and when the probabilities become relatively large, as in extreme old age, the number of cases becomes small. It follows, therefore, that the normal curve of error should only be used with a certain amount of discretion. Partly, no doubt, owing to the series in which the particular volume is included, and partly, possibly, owing to Dr. Galbrun's

personal inclination, his book is more mathematical and less clearly identified with the business of life assurance than the English text-books. The actuary on the Continent is less obviously the man of business than the actuary in England.

As we have seen, Prof. Borel indicates at the end of his book the interesting developments which lie outside its scope; it is not belittling, but appreciative, to say that there is room for similar development beyond where Dr. Galbrun's book ends, and that comparatively little has yet been done.

Electrical Instruments.

(1) *Electrical Measuring Instruments.* Part 1: *Commercial and Indicating Instruments.* By Dr. C. V. Drysdale and A. C. Jolley. Pp. 440. (London: Ernest Benn, Ltd., 1924.) 55*s.* net.

(2) *Electrical Vibration Instruments: an Elementary Text-book on the Behaviour and Tests of Telephone Receivers, Oscillographs, and Vibration Galvanometers.* (Engineering Science Series.) By Prof. A. E. Kennelly. Pp. xi+450. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1923.) 30*s.* net.

(1) IN the preface to their book on "Electrical Measuring Instruments," the authors state that "some apology would seem to be necessary for issuing yet another book on electrical instruments." It is true that a certain number of books of varying merit have appeared within the last few years, but the authors need be under no apprehension as to the need for the book which they have just published.

A book on electrical measuring instruments such as that which has been produced by Messrs. Drysdale and Jolley is of permanent value. It contains a fund of information about their design, the materials used in their manufacture, and the precautions that should be taken to secure accuracy, which will render it of very great value to instrument makers and electrical engineers. If one tests the book by looking for information on the less-known instruments, one seldom fails to find it. The only serious criticism which may be offered is the comparatively meagre information given about the qualities of cobalt steel. This material is being used in increasing quantities in Great Britain, and a large amount of research work on it has been carried out within the last few years.

The volume opens with a short account of the general principles involved in the measurement of electrical currents. The second chapter deals with mechanical design, and the various types of ammeter, voltmeter, and wattmeter are classified in accordance with their methods of control. Much useful information is given on such subjects as the properties of cylindrical spri and the arrangement of damping vanes. There is interesting note on pivots and on the methods manufacturing them to ensure good wear. In t and the following chapters such matters as the mounti of the series resistances of voltmeters, the design reactances for minimum power factor, the constructi of condensers with zero temperature coefficient, t methods of constructing pointers and scales, and leading in the conducting wires to instruments, discussed with great care and thoroughness. It the study of points like these that makes the differe between a good instrument and a bad one. Chap. deals with the quickness of action of instrumen and the considerations in the design that are importa from this point of view; fundamental electrostatic a magnetic theory is discussed, and among other matt the legal definitions of the units of current volta and resistance are included, and also some elabor tables of the working constant of instruments ma by different manufacturers.

One of the most useful parts of the book is Chap. which deals with the properties of electrical materi After a general account of the ordinary materials u as conductors, and those employed for insulating wir some figures are given for the most suitable curr densities to use in ammeter coils, and for the resi ance per volt in voltmeters. The thermo-elect properties of alloys are discussed in detail, and the p perties of the material known as "Therlo," which h been produced in the United States as a substitute manganin, are included. Some interesting data given of the dielectric strength and insulation resista of dielectrics. Evershed's well-known work on the eff of moisture on insulation is dealt with, as well as less-known work of Thornton on dielectric constan No account of insulating materials nowadays is compl which does not give some data relating to bake and its derivatives, and a good deal of information to be found about it, as well as about bitumen a impregnating materials. In dealing with magne substances, some useful data are given of the Heus alloy, including its hysteresis loss for a good range flux density. Yensen's vacuum iron is mentioned, a figures relating to it are given. The remaining chapt of the book deal with the properties of the princi types of instrument, namely, moving coils instrume soft iron instruments, dynamometer types of vo meters, ammeters, and wattmeters, hot-wire inst ments, and electrostatic instruments.

The figures and tables that are included in th chapters must have involved careful and elabor research, both in obtaining the necessary data a in classifying them. They provide a very valua

compendium of information about present-day instruments.

This book should be on the shelves of all electrical engineers and instrument makers.

(2) Dr. Kennelly's work on telephone receivers and other vibrational instruments is well known, and his method of considering the characteristics of telephone receivers as reciprocating electric motors has been widely recognised. He says in the preface, "The basic idea in the subject-matter is that every electrical transformation instrument possesses a motional impedance diagram, which is its fundamental form and is capable of disclosing many electro-mechanical characteristics of the instrument."

The book starts with an account of the Bell telephone receiver, and describes the various types which are now being manufactured. A considerable part of the subject-matter in the following chapters describes the researches Dr. Kennelly and his assistants have made on the vibration of the telephone diaphragm, and the reproduction of these papers into a book will be of great value to those who are interested in this subject. Nowadays, when the clear reproduction of speech and music is occupying the attention of so many people interested in broadcasting, the book should be of special interest. Not only does Dr. Kennelly deal very thoroughly and completely with the telephone receiver, but his book also contains a very good account of the various forms of vibration galvanometer which are now in use in light-current laboratories, as well as many of the different forms of oscillograph. In this connexion the oscillographmeter which Dr. Kennelly has devised is described. All those who are interested in light-current electrical measurements and the development of the telephone will find that this book is a necessary addition to their libraries.

Mendelian Studies.

Studia Mendeliana: ad centesimum diem natalem Gregorii Mendelii a grata patria celebrandum. Adiuvante ministerio Pragensi edita. Pp. 415. (Apud "Typos," Brunae, 1923.) 50 Kč.; 1½ dollars.

THE centenary of the birth of Gregor Mendel was celebrated at Brunn in 1923 by an international meeting of biologists. In "Studia Mendeliana" are collected twenty-four papers written in honour of the occasion. The inclusion in this volume of several papers on general evolution, of others on cytology, anthropology, the evolution and inheritance of sex, and lastly on the transplantation of tissue in relation to specific difference, illustrates the variety of the modern developments which have grown out of Mendel's fundamental discovery.

Among the papers on evolution is one by Prof. Lotsy on the importance of hybridisation in the production of new forms both in Nature and among domesticated races. Prof. V. Haecker writes on the origin and classification of racial characters, and advocates a close analysis of their occurrence in related forms from an evolutionary point of view. Prof. Witschi discusses the theory of orthogenesis, specially in relation to the evolution of sex. He regards sex differentiation as forming an orthogenetic series, culminating in forms with complete sex differentiation and determination at the reduction division. But the coincidence between sex determination and the reduction division is unessential, as shown by haploid and diploid hermaphrodites in animals and plants. From Witschi's own experimental work on rudimentary hermaphroditism and sex inheritance in local races of Rana, he concludes that they represent stages in the passage from the hermaphroditism of the Chordata to the highest forms of sex differentiation and determination at the reduction division. Differences between the local races of Rana he attributes to quantitative changes in the sex genes, brought about by indirect action of external conditions—an interpretation closely akin to that of Goldschmidt in his work on inter-sexes in Lymantria.

Working on Drosophila, Prof. Mohr has found a new case of the interesting phenomenon named by Bridges "deficiency," this term indicating the loss or inactivation of a section of a chromosome involving several genes. Hitherto such cases have been found only in sex-linked characters, but here the second chromosome is affected. Mohr makes the suggestion that all the dominant mutations in Drosophila which are known to be lethal when homozygous may turn out to be due to "deficiency." A report on the progress in the cytological and genetical investigation of the genus Crepis is made by Babcock, Collins and Mann. It is remarkable that the cross between *C. setosa* with four pairs, and *C. biennis* with twenty pairs of chromosomes, has given a hybrid with twenty-four pairs of chromosomes, and this hybrid has proved to have some degree of fertility. The authors regard this as an indication that more than one pair of homologues exist in the *C. biennis* group.

Dr. W. E. de Mol writes on heteroploidy and cross-fertility in *Hyacinthus orientalis*. He found both diploid and heteroploid forms to be self-sterile, but cross-fertilisations in general gave good seed. Heteroploid forms frequently arise as bud sports on diploids, and it is of special interest that these will not cross with the forms from which they derive.

In her essay on the transplantation of living tissue, Frl. Erdmann discusses the work of Leo Loeb on the

"individual differential" in newly-born rats and guinea-pigs of known breeding. Loeb found that the closer the relationship the more successful were the transplantations. The slightest difference in relationship affected the results, even brother to brother transplantations being more successful than those from parents to children. From the work of Spemann it is known that such individual distinctions arise during the development of the embryo, and Erdmann and others have suggested a parallelism with interspecific fertility. Nevertheless, Loeb has shown that in *Rana temporaria* these distinctions are independent of, or subsidiary to, the specific differential. Of great interest is Erdmann's observation that interspecific transplantations in Rana are facilitated by an intermediate period of growth of the graft in various media. C. P.

Oceanography.

An Introduction to Oceanography: with Special Reference to Geography and Geophysics. By Prof. James Johnstone. Pp. xii+351. (Liverpool: University Press of Liverpool, Ltd.; London: Hodder and Stoughton, Ltd., 1923.) 15*s.* net.

OCEANOGRAPHY is an extraordinarily composite subject; it touches on almost every branch of science, from the astronomical theory of the tides to the biological significance of the plankton. For this reason it is difficult for the student to weld the very varied facts at his disposal into a single consistent body of knowledge. Herein lies the value of a book such as this, which brings out the general theory in a clear and very readable manner without unnecessary detail.

After a brief description of its morphology, the probable origin of the world-ocean is discussed. This leads naturally to the consideration of its depth and the character of the bottom and the nature of the ocean margins. Great stress is rightly laid on the very small vertical scale of the surface features of the earth. Two chapters then follow on the chemistry and physics of sea-water. In the chapter on the tides, the author has attempted with very fair success the difficult feat of a non-mathematical exposition of the theory of their production. The oceanic circulation is described and explained very clearly, so that the significance of the underlying causes can be fully appreciated. The final chapter on secular changes in the ocean is perhaps the most interesting and suggestive, and fixes in the mind the ideas put forward in the rest of the book.

When so wide a field is covered it is almost impossible for the standard to be maintained throughout. The chapters on the chemistry and physics of sea-water are not quite so good as the rest of the book. In the section on the hydrogen ion concentration of sea-water, the notation has been confused, the symbol pH h used at first (p. 149), where it is obvious that the hydr ion concentration, C_H, is referred to, although " pH " is correctly defined and expressed (p. 153). the description of the effect of cooling a solutio sodium chloride (p. 185) it is incorrect to say " The quantity of ice formed increases, the quanti sodium chloride crystals formed also increases and concentration of the solution remaining unfr increases." As the eutectic is approached, *either* ice or pure sodium chloride crystals separate accor to the initial concentration of the salt. Not until eutectic is reached do salt crystals and ice separate together (*vide* "A System of Physical Chemist vol. ii., W. C. McC. Lewis, pp. 247 and 248).

The explanation on page 186 of why ice formed sea-water floats is strange. The expansion of w on solidification has been overlooked. The ice for from sea-water is not only lighter than sea-water is lighter than fresh water, since its specific gra is about 0·92 (*vide* "Handbuch der Ozeanograp Band I., Dr. O. Krümmel, p. 507).

Apart from these sections the book is excellent, it is hoped that they will be revised in the next edi The illustrations are well done, and there is a appendix which can be referred to for literature. T are few misprints; the formula at the top of p. should read "$Q = P.K/T$," and on p. 191, line " more" should read "less," while on p. 187 "Na should read "Na_2SO_4."

Our Bookshelf.

(1) *Outlines of Fungi and Plant Diseases: for Stu and Practitioners of Agriculture and Horticulture.* F. T. Bennett. Pp. xi+254. (London: Macm and Co., Ltd., 1924.) 7*s.* 6*d.* net.

(2) *Practical Botany.* By Rai Bahadur K. Rangac Pp. iii+114. (Madras: Government Press, 1 18 rupees.

(3) *British Mosses and How to Identify Them.* J. H. Crabtree. (How to Identify Series, No. Pp. 63. (London: The Epworth Press, 1 1*s.* 6*d.* net.

(4) *Plant Studies.* By Prof. James A. Todd. (Fou tions of Nature Study Series.) Pp. 151. (Edinbu A. Baxendine and Sons, 1924.) 2*s.* 6*d.* net.

(5) *The Nature-World of London.* By Walter Johr 1: Trees and Plants. Pp. viii + 118 + 8 pl (London: The Sheldon Press; New York Toronto: The Macmillan Co., 1924.) 3*s.* net.

(1) Mr. Bennett's book on fungi and plant dise has been written more particularly for student agriculture and horticulture. It should serve purpose very well. The first part gives a ger account of the fungi, with a short classification the life histories of a number of members of the var groups. The second part deals with plant disease

sch. The modern study of this subject only began bout 1866, but has developed in many aspects in cent years. The chapter dealing with the general pects of parasitism, such as infection, resistance, and munity, might very well have been considerably tended. In later pages all the better known fungus eases of crops, from mycetozoa to rusts and bacteria, e clearly described, together with their effects on e host plant and methods of treatment. In conxion with wheat rust, the important developments ce the "bridging" theory was generally held are ly referred to in a footnote. The volume will be eful to all those who wish to acquire a general knowlge of plant diseases. Its conciseness and arrangent will appeal to the student.

(2) The second work on our list is a small book laboratory exercises to accompany the author's Manual of Elementary Botany for India." The ants studied and illustrated are chiefly tropical forms ch as *Dolichos lablab*, *Arachis hypogæa*, and *Andropogon sorghum*, which are not generally examined in uropean laboratories. The figures, many of which e photomicrographs, would have been clearer in some ses if they had been taken with a higher magnification. he book is in three sections, the first dealing with the orphology of root, stem, leaf, flower, and fruit; the cond with physiology, in which various simple periments are outlined; and the third with Cryptoms.

(3) The author gives in small space popular descripons of about sixty of the commoner British mosses. n each page two species are described, with photoaphs of the species on the accompanying page. echnical terms are avoided, but habitats, and in some ses localities, are given. This popular treatment ould enable moss-lovers to recognise genera, and in any cases species, without much difficulty. The notographs usually show the habit without attempting to portray any further detail.

(4) Mr. Todd's book is one of a series on the foundaons of nature study. It is intended for teachers who e conducting school classes in this subject. Beginning ith a short chapter on the cellular structure of plants, ere follow others equally brief on the various plant gans, vegetative reproduction, plant identification, ees and cryptogams, with a final chapter of notes on ology. The definition of a flower (p. 53) is not very appy, and some of the figures suffer from their small ze. Those who have had no previous acquaintance ith botany would find it of greatest use.

(5) The charmingly written little book of Mr. Walter ohnson is full of lore concerning the trees and other lants of the London area, as they are known to the uthor. Botanist and layman alike can find entertainent in its pages. The historical trees referred to nclude Nelson's mulberry and Captain Cook's "cotton ree," which is a balsam poplar. Chapters on the wild owers and weeds of London are equally entertaining ccounts of plants found in the commons, gardens, and pen spaces of London. In the final chapter on ondon's mushrooms and toadstools, many of the ommon forms are mentioned, including some of those ound in wine cellars. It is to be hoped that the uthor's promise of a further volume on other phases f Nature in London will be carried into effect.

Kitāb al-'ilm al-muktasab fī zira'at adh-dhahab: Book of Knowledge acquired concerning the Cultivation of Gold. By Abu'l-Qāsim Muḥammad ibn Aḥmad al-'Irāqī. The Arabic text edited with a translation and introduction by E. J. Holmyard. Pp. iv+62+53. (Paris: Paul Geuthner, 1923.) n.p.

MR. HOLMYARD in the introduction to his book remarks justly that "the investigation of the original sources of Arabic chemistry has scarcely yet been attempted." The most important work was that of Berthelot, yet owing to the limited range of works studied, particularly in the case of Jabir ibn Hayyān, it is likely that some of the conclusions of the great French historian of chemistry may require modification. A reaction against the rather premature generalisations of Berthelot, which are most warmly supported by those who have no knowledge of the original sources, has undoubtedly set in, and the further investigation of Arabic sources by those competent to undertake the work will no doubt provide information of great interest to students of the history of chemistry.

The text published by Mr. Holmyard is a small treatise by a thirteenth-century Arabic alchemist. The intrinsic interest of the work is not very great: the theory that all metals are really the same and differ only in unessential properties, which may be removed, is Aristotelian, but the assumption that "the metallic substance freed of such accidental properties is gold" seems unusual, and, as Mr. Holmyard says in his introduction, was opposed by other Arab chemists, including Ibn Sina ("Avicenna"), who held that each metal is distinct. The author speaks of the "two leads," the "two coppers," and so on; some materials will "turn copper yellow with the yellowness of gold," but "do not make it complete." As the Latin Geber says, *tutia* will "citrinise copper of a good yellowness," but he adds that it is to be taken only for "the lesser work," *i.e.* for deception only. The comparison of the elixir, which is to transmute metals, with the remedy, which is to cure disease, is instituted. Many names of Greek-Egyptian alchemists, such as Zosimus, Agathodemon, Maria, etc., are mentioned: the first as "the Jew"; Khalid ibn Yazid and Marianus also appear. The "Art of the Egyptians" is chemistry. All this points clearly to the sources: Arabic chemistry came from Hellenistic Egypt in the first instance, and one of the important questions to which further research will disclose an answer is how much original work the formerly much vaunted Arabic alchemists really did.

Mr. Holmyard must be congratulated on his book, and readers will look forward to the conclusions he will perhaps draw from the study which has enabled him to produce it. Of the Arabic text the reviewer is unable to offer an opinion, but it has been looked through by Prof. Browne and Mr. Steele, who are experts.

J. R. P.

L'Hérédité. Par Prof. Émile Guyénot. (Encyclopédie scientifique: Bibliothèque de Biologie générale.) Pp. 463. (Paris: Gaston Doin, 1924.) 19·80 frs.

THE scientific experimental study of heredity may be said to have begun with the present century. The views of the early hybridisers were too vague, and were based upon results too varied and indefinite to lead anywhere. Moreover, the work of the nineteenth

century was required to build up an edifice of knowledge concerning organic structure and development, the nature of sexual reproduction, and the structural basis of heredity, before definite views of the laws of inheritance could be propounded and accepted. But in the last twenty-four years advance has been rapid, because all these and other lines have converged upon the solution of the central problem of heredity. Where all was formerly hazy and nebulous, results are now seen to be clean-cut and precise, continually opening up further vistas of understanding concerning the relations between the details of organic structure as we find them, and the laws and exceptions to the laws of inheritance as they are developed by experimental work.

While the advances in Mendelian heredity, sex chromosomes, etc., have been rapidly incorporated into biology on account of their fundamental character, yet to the lay mind heredity remains for the most part an unintelligible and almost mystical "force." Even the medical profession remains in an uninstructed condition regarding a subject which vitally concerns their daily activities.

Any book which spreads the modern knowledge of heredity is therefore to be welcomed, and the volume before us, by Prof. Guyénot, should be very useful in this respect for French-speaking peoples. The author's definition of heredity is worth quoting: "L'hérédité consiste dans la totalité des réalisations morphologiques ou physiologiques que le descendant tient de ses parents."

The volume is divided into three sections. The introduction begins with a chapter on the continuity of living matter as the basis of heredity. The sections deal with the laws of hybridisation, the chromosome theory of heredity, and Mendelian anomalies. In the last, such topics as hyperdactyly in fowls, lethal factors, cytoplasmic inheritance, and xenia are discussed. The final chapter is devoted to inheritance in man. While containing little or nothing that is new to the geneticist, the book presents a useful summary of recent advances in this field. The number of Drosophila mutations has now reached more than 300, not 100 as the author states. R. R. G.

Human Protozoology. By Prof. Robert W. Hegner and Prof. William H. Taliaferro. Pp. xix+597. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1924.) 4.50 dollars.

THIS work has been prepared primarily for the use of students in the authors' course of protozoology in the School of Hygiene of the Johns Hopkins University, but it will be of great use to students pursuing similar courses in other institutions, and to medical officers who desire a concise statement of the facts of protozoology. Emphasis is rightly laid on the value of a study of parasites from lower animals, which are often more easily obtained than the allied species occurring in man, and serve as excellent material for practice in technique and in the study of life-cycles.

In the general introduction to the organisation of the protozoa, structure and modes of division are considered. The following chapters deal in turn with the main groups of protozoa, the structure and life-history of representative genera and species being described and careful reference made to the methods of spread those which occur in man. A chapter is devoted the genetics and the physiology of reproduction in t protozoa, and a final chapter gives useful informati on the diagnosis of intestinal protozoa. A well-chos list of books and memoirs on protozoa occupies sor fifty pages, there is an adequate index of authors a of subjects, and the volume is excellently illustrat by clearly drawn figures.

In reviewing a work which is so well done it is almo ungracious to ask for more, but here and there t authors might consider whether in their next editi they could add a few further details; *e.g.* in the chapt on Hæmosporidia (exclusive of malaria) it would useful to have some account of the life-history of Pir plasma, incompletely known though it be, and *Theileria parva*, a short account of Proteosoma, and reference to Mrs. Adie's work on Hæmoproteus.

The authors are to be congratulated on the produ tion of this excellent manual.

A Check-List of British Birds: With a Short Accou of the Status of Each. Compiled from "A Practic Handbook of British Birds." By H. F. Witherb Pp. 78. (London: H. F. and G. Witherby, 192 3*s.* 6*d.* net.

ORNITHOLOGISTS will welcome this little book, which printed on one side only of the paper for convenien in labelling or for the making of notes. The fact th it is taken from the "Practical Handbook of Briti Birds" is a sufficient guarantee that it is up-to-date a correct in all matters ornithological and nomenclatori

From the biological point of view, it is very i structive to look down the pages of the book and no which of the species remain binomial, which have r into trinomials. The latter, of course, are in the gre majority—a sign of the enormous amount of ge graphical variation which patient research reveal The problem is to understand why some species sho this tendency to break up into geographical races subspecies, while others remain invariant. The la of variability in some of these may be apparent onl due to our ignorance; but this cannot be true of t Chough, the Snow-Bunting, the Brambling (the specif name of which, by the way, contains a misprint), t Meadow-Pipit, the Waxwing, the Lapwing, the Redwin and many others. Sometimes whole groups, such the Tits or the Wheatears, seem to show excessi variability, while the Anseres contain an unusual large proportion of "unsplit" species.

The evolutionary biologist should pay more attentio to the rich mine which the labours of the systematis most notably in the group of birds, have opened u for him. J. S. H.

Exercises on Ordnance Maps. Selected and arrange by C. H. Cox. Pp. 60+12 maps. (London: G Bell and Sons, Ltd., 1924.) 1*s.* 9*d.*

ELEMENTARY and advanced exercises are based o twelve sections of different scale ordnance maps various styles. Concentration on map work of th nature is the best introduction to the study of geography Even if some of the questions are a little far-fetched a exercises on the maps, the book is excellent and deserv to be widely used in schools. R. N. R. B.

Letters to the Editor.

The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*]

On the Vibrations of Air in Organ-Pipes of Unusual Shapes.

IN 1867–68, when I was Principal of La Martinière College, Calcutta, I made some experiments on organ-pipes in conjunction with the Cathedral organist, Mr. Frye, who was trying to rebuild a small organ on which to practise in his own room. His problem was how to get pedal-tones from pipes smaller than the regulation minimum, namely, 8 ft. stopped diapason, a very inconvenient size in an ordinary house. I studied his "Hopkins and Rimbault," and became quite fascinated with the subject, chiefly on its scientific and mathematical side.

Mr. Frye supplied the first hint for a solution of the problem. He noticed how low were the tones given by a large bottle with a small neck, when blown across the mouth like a flute. For example, a bottle which stands easily in a space 1 ft. high on a base $4\frac{3}{4}$ in. in diameter gives the note Bass E♭, the pitch of an open diapason pipe about 6 ft. 8 in. from mouth to top. But the practical difficulties in the way of making a pedal "bottle-stop" proved too much for him.

I found my available text-books useless, and had to invent the mathematical investigation for myself. A "bottle-pipe" is really two pipes of unequal diameters, joined together by a flange from the outer edge of the smaller pipe with the mouth-piece, to the inner edge of the larger stopped pipe. The text-books give the formulæ of vibration in a uniform cylinder, either open or stopped. I took these formulæ for the two separate parts, and made them fit at the junction by the two conditions, that the air-pressures must be the same for both, and that with each swing the volume of air thrown from the small part into the large must be equal to the volume returned by the large into the small. Hence I deduced the formula

$$\tan mh \,.\, \tan mk = \frac{\text{area of mouth-part}}{\text{area of stopped part}} = \frac{r^2}{R^2},$$

where h and k are the lengths of the two parts, r and R their radii, and m is proportional to the vibration-rate of this composite pipe, so that $ml = \pi$, if l be the length of the open diapason of the same pitch.

This formula shows that h and k are interchangeable, so that the mouth-part may be short and the stopped part long, or the reverse, without altering the pitch. It is also easy to see that the lowest note will be obtained by making the two parts of the same length. This form gives us a new kind of organ-pipe which I call a *Bicylindron*. If r be the radius of the mouth-part, and R that of the stopped part, and h the length of either half, then

$$\tan^2 mh = \frac{r^2}{R^2} \text{ or } \tan mh = \pm\frac{r}{R},$$

where as before $ml = \pi$ gives the length l of the "tone," as estimated by organists; *i.e.* Bass C = 8 ft. tone; Tenor C = 4 ft. tone, etc.

That the above formulæ are accurate enough for practice I have proved by making zinc models with suitable measurements.

It can easily be seen from this formula that a *Bicylindron* "stop" can be made of two varieties. If $r < R$ the pitch will be lower than that of a stopped diapason of the same total length, $2h$. If $r > R$ the pitch will be higher; but it will be lower than that of an open diapason of length $2h$. For a pedal-stop, of course, r must be less than R.

But "Hopkins and Rimbault" gave another solution. There is an organ in Oxford, with a *Pyramidon* stop, invented by Ouseley. Each pipe is an inverted pyramid, closed at the base, with a mouthpiece at the narrow end, near the apex. The writer is astonished at the low note such pipes give in comparison with their height; but he attempts no explanation of the mystery. To the mathematician such a pipe is merely a conical pipe, closed at the broad end. My copy of Besant's "Hydrodynamics," said not a word about conical pipes, though almost all reed-pipes in an organ have open conical resonators. So I had to invent the theory for myself, and found out the formula, which gives the fundamental note and the overtones, namely,

$$\tan mh = mk,$$

where h is the distance from mouth to base, and k from vertex to base, m having the same meaning as before. I verified this formula by a few small zinc models. It is not given in Basset's "Elementary Hydrodynamics" (1890), nor in Lord Rayleigh's "Theory of Sound" (1894). The latter works out the theory of open conical pipes, and shows that they are, in pitch and in harmonics, equivalent to cylinders, as organ-builders know by experience. Basset perversely limits himself to conical pipes *without any mouthpiece*; so that his investigation is useless for the *Pyramidon*. But I have worked out the problem from the data given by both authors, and deduced from either the formula given above. Both authors give the formula for the mouthless pipe, namely,

$$\tan mk = mk,$$

which is merely a particular case of my formula, when $h = k$; *i.e.* when the mouthpiece is run down to a mere point at the vertex.

From the formulæ given above, mathematical readers can prove that, space for space, a *Bicylindron* always beats a *Pyramidon* for depth of pitch. For example, if the breadth at the stopped end be 9 inches for both, and the breadth at the mouth 3 in., and the height from mouth to stopper be 2 ft., the *Pyramidon* gives nearly a $6\frac{1}{2}$ ft. tone, while the *Bicylindron* gives a tone rather lower than $9\frac{2}{3}$ ft.

But the all-important consideration has not yet been noticed. In an organ everything depends upon "quality of tone"; and it is now an established axiom that quality of tone depends upon the proportionate admixture of harmonic overtones. The standard musical instruments—violin, piano, and organ—all give the complete series of natural musical harmonics, the vibration-rates of which are proportional to the series

1, 2, 3, 4, 5, etc., *ad infinitum*.

There is one exception in the organ. The stopped diapason can give only the odd harmonics, 1, 3, 5, 7, etc. The octave harmonics, which make the tone bright and clear, are all cut out. Thus a stopped diapason can give a soft sweet tone, but can never give the full rounded ring of the open diapason. Its chief advantage is that it takes up only half the space and saves half the cost in materials.

Now the formulæ given above prove that the overtones of a *Pyramidon* are all incommensurable and therefore unmusical. The best voicer in the world can make nothing out of it beyond a dull humming note. But with the *Bicylindron* all we have

to do is to make the ratio $r : R$ exactly equal to $\tan \pi/n$, where n is any integer, and we shall get the harmonic sequence

$$1,\ n-1,\ n+1,\ 2n-1,\ 2n+1,\ 3n-1,\ 3n+1,\ \text{etc.}$$

For pedal notes the best values of n are 5, 7, or 9; these will give octave harmonics. If we take $n=5$ we shall get a pipe shorter than the stopped diapason of the same pitch in the ratio of 4 : 5; but its harmonic overtones will be the series

$$1,\ 4,\ 6,\ 9,\ 11,\ 14,\ 16,\ \text{etc.},$$

which should give a far better quality than the ordinary stopped diapason.

But the best of all for quality is the $\pi/3$ *Bicylindron*, the length of which is two-thirds that of the open diapason of the same pitch. This pipe has the harmonic sequence

$$1,\ 2,\ 4,\ 5,\ 7,\ 8,\ 10,\ 11,\ 13,\ 14,\ 16,\ \text{etc.}$$

This pipe, if properly voiced, should make a solo stop with a unique loveliness of tone. Experimentally I have proved the sequence 1, 2, 4, and 5.

I worked out my formulæ in the case of a double conical pipe, made of two cones joined together at the broader equal ends, each tapering to a smaller mouth in opposite directions. The result can be found by a very pretty calculation from the formulæ given by Basset or Lord Rayleigh; it is

$$m \sin m\mathrm{H} = \left(\frac{1}{k}+\frac{1}{k'}\right) \sin mh \sin mh',$$

where $\mathrm{H}=h+h'$; h and k have the meaning given above for the *Pyramidon*; h' and k' the corresponding quantities for the second cone; and m gives as before the vibration-rate of the whole pipe, which is of lower pitch than an open cone of the same length. This double pipe is intended for reed-stops, which need a cone tapering to the narrow reed-tube. By taking $h'=h$ or $h/2$ we can get all the harmonics of the open cone h'; and by giving suitable values to k and k' we can ensure that the fundamental tone shall be an exact double octave below the open cone h', thus gaining the conditions for good quality. Hence we find in either case

$$\frac{1}{k}+\frac{1}{k'}=\frac{\pi}{2h}.$$

In 1868 I made four pipes on this plan, using some harmonium reeds I had by me, of pitch Tenor C, D, E, and F. Mr. Frye tried them in the Cathedral organ. We both agreed that the tone was very beautiful, when it came on. But there was a distinct burr at the beginning and end of the tone, and the pipes were so "slow of speech" that in a quick run they never spoke at all. Such "free reeds" are probably inappropriate: they are never used by English organ-builders. But the experiment shows that in expert hands a reed-pipe of this kind might be made with a tone of unique beauty, free from all defects of "speech."

JAMES A. ALDIS.

The Quantum Theory of Dispersion.

IN a recent letter to NATURE (May 10, p. 673) Dr. Kramers advanced a quantum theory of dispersion which is a generalisation of the theory of Ladenburg. The formula proposed by Kramers for the polarisation of an atom when put in a wave is his formula (5). This formula is stated by Kramers to satisfy the condition demanded by the Correspondence Principle, namely, that the dispersion due to an atom in a state of high quantum number is the same on the classical and on the quantum theories.[1] The presence of the second term has been introduced by Kramers for this purpose. From the point of view of the virtual oscillators of Bohr, Kramers, and Slater, the second negative term of Kramers is somewhat dissatisfying because an oscillator would give rise only to a term of the first positive type.

The present writer has been also considering the question of interaction between radiation and quantised atoms in connexion with the question of the Brownian movement of atoms in black body radiation. A picture similar to the virtual oscillator finds application also in that field. However, the exact form of the interaction has been conjectured by the writer to be somewhat different from that proposed by Kramers.

The difference can be illustrated in the case of a linear oscillator. In this case the expression of Kramers becomes at long wave-lengths

$$P=[n-(n-1)]\frac{e^2}{m}\frac{1}{4\pi^2(\nu_i^2-\nu^2)}=\frac{e^2}{m}\frac{1}{4\pi^2(\nu_i^2-\nu^2)}.$$

The same result may be also derived as

$$P=[\tfrac{1}{2}+\tfrac{1}{2}]\frac{e^2}{m}\frac{1}{4\pi^2(\nu_i^2-\nu^2)}.$$

In this manner the negative term may be avoided. In order to satisfy the Principle of Correspondence the dependence of P on ν must be in general slightly more complicated than that for the oscillator. This dependence can be derived from a consideration of a "virtual orbit" rather than a virtual oscillator. (I am indebted to Prof. Van Vleck for this term.) The "virtual orbit" has the same frequency as the "virtual oscillator." However, its reaction to the external field is comparable with that of an electron the orbit of which is the mean of all the orbits between the two stationary states. (The meaning of "mean" is of necessity somewhat indefinite.) It is clear that in the general case a properly taken sum of the contributions of the various ν_i^a, ν_i^e will give the required result. Thus it is sufficient to attribute to a transition between a quantum state of quantum number $(n_1+\tau_1, \ldots n_u+\tau_u)$ to $(n_1, \ldots n_u)$ one half of the contribution to the polarisation on the classical theory due to the terms in frequencies $\tau_1 w_1+ \ldots +\tau_u w_u$ (in Bohr's notation) in order to satisfy the Principle of Correspondence.

It appears that the form of the theory here outlined is better capable of explaining dispersion at long wave-lengths (say for an atom in the normal state) than the form of Kramers because the characteristics of the motion are of greater influence on the "virtual orbit" than on the "virtual oscillator" point of view. By introducing a properly taken mean, one may hope to obtain the influence of a static field as a limiting case of a field considered in the theory of dispersion.

G. BREIT.
Physics Department,
The University of Minnesota,
Minneapolis, Minn.

THROUGH the courtesy of the Editor of NATURE I have been permitted to see Mr. Breit's letter, and I welcome the opportunity thus afforded me to add some further remarks on the theory of dispersion in order to elucidate some points which were only briefly touched upon in my former letter.

In addition to the empirical applicability of the dispersion formula of the type (4), the arguments which

[1] Prof. J. H. Van Vleck, of this University, has shown, in a publication which is to appear soon, that this formula satisfies the Correspondence Principle for the case of the general non-degenerate multiple periodic orbit.

e to the proposal of formula (5) rested on the
ssical expression for the amplitude of the secondary
velets which an incident plane wave sets up in a
stem of electrified particles. Consider a system,
e motion of which is of multiple periodic type, and
e the electrical moment M in a given direction of
e undisturbed system, which is supposed to possess
independent fundamental frequencies $\omega_1, \ldots \omega_u$,
represented by

$$M = \Sigma C \cos(2\pi\omega t + \gamma), \quad . \quad . \quad . \quad (1^*)$$

ere the frequencies $\omega = \tau_1\omega_1 + \ldots \tau_u\omega_u$ and the
plitudes C depend on the quantities $I_1, \ldots I_u$,
ich in the theory of stationary states are equal
integer multiples of Planck's constant h, as well
on the set of integer τ-values characteristic for the
sidered harmonical component of the motion.
It next the incident wave be linearly polarised with
electrical vector parallel to the given direction,
d let the value of this vector at the point where the
stem is situated be given by $E \cos 2\pi\nu t$. The
ctrical moment of the forced vibrations of frequency
et up in the system will then be equal to

$$P = \frac{E}{2}\Sigma\frac{\partial}{\partial I}\left(\frac{C^2\omega}{\omega^2 - \nu^2}\right)\cos 2\pi\nu t, \quad . \quad . \quad . \quad (2^*)$$

ere $\frac{\partial}{\partial I}$ stands as an abbreviation for $\tau_1\frac{\partial}{\partial I_1} + \ldots$
$\tau_u\frac{\partial}{\partial I_u}$.

Now in the limit of high quantum numbers the
equencies of the spectral lines connected with the
fferent possible transitions will coincide asymptotic-
ly with the frequencies of the harmonic components
the motion, and, according to the Correspondence
inciple, the energy of the spontaneous radiation
r unit time combined with each of these frequencies
ill be asymptotically represented by the expression
$\frac{(2\pi\omega)^4C^2}{3c^3}$. We will now make the assumption that,
this limit, formula (2*) gives an asymptotical
pression for the dispersion. In order to obtain
general expression holding for all quantum numbers
e note that, while the frequencies ω of the harmonic
mponents of the motion are given by the general
rmula

$$\omega = \frac{\partial H}{\partial I},$$

e exact expression for the frequencies of the
ectral lines is given by the general quantum relation

$$\nu_a = \frac{\Delta H}{h},$$

here ΔH signifies the difference of the energy H in
vo stationary states for which the values of $I_1, \ldots I_u$
iffer by $\tau_1 h, \ldots \tau_u h$ respectively. The assumption
resents itself that, in a generalisation of formula
2*), the symbol $\frac{\partial}{\partial I}$ has to be replaced by a similar
ifference symbol divided by h. This is just what
as been done in establishing formula (5). In fact,
is formula is obtained from (2*) by replacing the
ifferential coefficient multiplied by h, by the differ-
nce between the quantities $\frac{3c^3A^ah}{(2\pi)^4\nu^{a2}(\nu^{a2} - \nu^2)}$ and
$\frac{3c^3A^eh}{(2\pi)^4\nu^{e2}(\nu^{e2} - \nu^2)}$ referring to the two transitions coupled
espectively with the absorption and emission of the
pectral line which corresponds with the harmonic
omponent under consideration.

Apart from the problem of the validity of the underlying theoretical assumptions and of any eventual restriction in the physical applicability of formula (5), the dispersion formula thus obtained possesses the advantage over a formula such as is proposed by Mr. Breit in that it contains only such quantities as allow of a direct physical interpretation on the basis of the fundamental postulates of the quantum theory of spectra and atomic constitution, and exhibits no further reminiscence of the mathematical theory of multiple periodic systems.

In this connexion it may be emphasised that the notation "virtual oscillators" used in my former letter does not mean the introduction of any additional hypothetical mechanism, but is meant only as a terminology suitable to characterise certain main features of the connexion between the description of optical phenomena and the theoretical interpretation of spectra. This point is especially illustrated by the appearance of negative as well as positive oscillators, which helps to bring out the new feature, characteristic of the quantum theory of spectra, that the emission and absorption of a spectral line is coupled with two separated types of physical processes. The fundamental importance of this general feature for the interpretation of optical phenomena is, as mentioned in my former letter, indicated by the necessity, pointed out by Einstein, of introducing the idea of negative absorption in order to account for the law of temperature radiation.

H. A. KRAMERS.

Institute for Theoretical Physics,
Copenhagen, July 22.

Lake Victoria and the Flow of the Yala River.

DURING a recent investigation into the epidemiology of sleeping sickness along the east coast of Lake Victoria, north of the opening of the Kavirondo gulf, I observed the following phenomena which I trust some readers of NATURE may be able to explain, for I cannot.

The river Yala, which enters the lake at this part of the coast, passes through swamps which are kept back from the lake by sand-banks. Having landed here I noted many channels cut through the sand, running inland from the lake. The local natives said, "These were made by our forefathers, six generations ago, to drain the swamps." I pointed out that at that moment (about 9.30 A.M.) the water was not running out *from* the swamp but *into* it from the lake at quite a considerable rate, which I thought might be two miles per hour.

The natives replied that the current ran thus from daybreak until two in the afternoon, when it was reversed and flowed back into the lake. This is the daily routine so long as the lake is at the higher levels of its seasonal variations; when it is low, in the dry season, the flow through these channels is always from the swamp.

I am much puzzled as to the explanation of this diurnal variation, which cannot be accounted for by changes in direction of wind. I was working along that coast for several weeks and soon noted that the breeze from lake to shore (westerly, here) does not commence before 9.30 A.M., often not till ten; until that time, from the small hours, there is a strong cool breeze from off shore.

I omitted to ask the natives in which direction the current flowed during the night: they had said "from daybreak," but that probably means merely the earliest time when they noticed it.

Since it occurred to me that the great loss which must take place from the open lake by evaporation during the heat of the day might conceivably lower

the level of the lake in the afternoon, I obtained readings of the level at Entebbe by the official recorder at 8 A.M., noon, and 4 P.M. On three successive days the records were as follows :

Date.	8 A.M.	Noon.	4 P.M.
July 2 . . .	10·42	10·42	10·42
,, 3 . . .	10·42	10·42	10·42
,, 4 . . .	10·41	10·42	10·41
,, 5 . . .	10·40	..	..

This explanation, therefore, is not possible, and indeed seems improbable in consideration of the vast size of the lake and the relatively small amount of water poured into it by the Kagera and smaller rivers, of which the Yala is one. The inflow would need to be very much larger in order to raise the level of the whole lake during a single night.

G. D. HALE CARPENTER,
Uganda Medical Service.

Entebbe, Uganda, July 5.

English Enemies of the American Slipper-limpet, *Crepidula fornicata*.

IN 1923 the present writer found a shell of a dead slipper-limpet (*Crepidula fornicata*) at West Mersea, Essex, bored extensively by the boring sponge *Cliona celata*. This year a good number of living slipper-limpets have been examined, and one, the fourth individual of a chain of 8 living ones, was found with the living sponge boring into the shell. In the shell of the dead animal the sponge could be seen to have bored through all parts including the shelf, but had been inhibited from perforating over almost the whole of the area on the dorsal side, where another slipper-limpet had been attached to it. In the living specimen the sponge can be seen to be forming a honeycomb mesh-work in the dorsal portion of the shell, but it has only perforated to the surface in the postero-dorsal region ; the shelf of the shell is also attacked and is almost perforated in places. On the part of the shell where the next individual in the chain was sitting there is a nodular deposition of calcareous matter over strands of the sponge tissue. This deposit has been laid down, not by the owner of the shell, but by the individual sitting on the shell, and undoubtedly as a reaction to the irritation caused by the sponge. Crepidula has, therefore, found an enemy in Cliona in its new environment, and it will be interesting to know to what extent the slipper-limpet will be attacked in future in view of its economic importance.

Crepidula has other enemies. I have observed the whelk-tingle, *Ocinebra* (*Murex*) *erinacea*, attack the shell of Crepidula and bore through to the body, and shells can be found on the oyster-beds also bored either by Murex or Purpura, but it is difficult to estimate whether the boring whelks are of much value in killing off numbers of Crepidula. Whitstable fishermen know that dabs, *Pleuronectes limanda*, eat Crepidula, and I have seen fresh slipper-limpets in recently opened stomachs of this fish, but it seems likely that many of these limpets are obtained from chains broken in the dredging operations. Mr. Luckhurst, of Whitstable, informs me that starfishes, *Asterias rubens* chiefly, attack Crepidula, especially in winter time, when the slipper-limpets have apparently been weak. Since Crepidula was introduced into England from America round about the year 1880, it will be interesting to know from time to time in the future what English marine animals become inimical to it. At present Crepidula appears to be maintaining its dominance in the rich waters of the Thames Estuary ; this year there is a great fall of spat in many places in the north-western portion of the Estuary, although for the last few years the spatfall has been below the average in most places.

Former Fertility of the Kalahari Desert.

PROF. J. W. GREGORY, in his article on my recent Kalahari pamphlet in NATURE of April 12, p. 5[illegible] objected to my citing the Sylphium of Cyrenaica as evidence of the former fertility of the desert. I also gave the wine palm, *Raphia monbuttorum*, as evidence for, whereas it formerly lived in the Egyptian oases it is now confined to the more humid regions further south. Hassanein Bey has recently given evidence to the same effect in the oases of Kufra and Ouenat. In the latter place he describes rock drawings of ostriches, giraffes, and other animals that require grassland, and could not possibly live in the desert as it is to-day. The fact that there are no camels shown indicates that the pictures were made before A.D. 640, when the Arabs arrived in Africa with the camels. Nowadays, life in Ouenat would be impossible without these animals.

In South Africa we have the same evidence in Bushman drawings of hippopotamus, rhinoceros, and other animals, where these could not live to-day although we know they lived all about here 100–150 years ago. The last lion, hippopotamus, and rhinoceros were shot in the neighbourhood by the fathers of people still living in Grahamstown. I have already given the evidence of the Yellow-wood (Podocarpus), the typical Knysna forest tree, still lingering on hills in Namaqualand in what is now practically desert, and a few specimens are found on isolated hills between there and Cape Town. Recently, however, I have been shown by my neighbour, Mr. M. Godlonton, a specimen of the Winterberg bamboo (*Arundinaria tessellata*, Monroe), growing in his garden, which is a striking proof of more humid conditions not very long ago. It was only one hundred and fifty years ago since Barrow, Lichtenstein, and le Vaillant saw our Karroo plains swarming with big game, as now in Uganda, and we have every reason to believe that at that time the slopes of the mountains were covered with bamboo forest as now on the Nandi plateau in Central Africa, and of which these few stray stragglers still survive.

The Winterberg is about 7000 ft. and some miles north of Grahamstown. E. H. L. SCHWARZ.

Chalky Boulder Marl at Hastings.

As relief workers in the Hastings district are continuously laying bare geological sections of first-class importance, and as the demands upon my time have precluded the possibility of my bringing the full details before scientific societies, I feel that geologists in general would be interested in a short account of them in the pages of NATURE. They relate not only to Wealden but also to Pliocene and Pleistocene times.

WEALDEN.—Excavations in the Wadhurst clay have brought to light a remarkable richness of both vegetable and animal life, particularly among the mollusca in which Nature has shown herself most energetic, not only in the cases of well-known genera and species of ordinary character—necessitating a revision of the Wealden mollusca—but in others she has shown great prodigality, some of the gastropods—dextral and sinistral—attaining a length, or height, of sixty feet

and upwards. These sections have also given the life-history of important rocks and rock-structures, and furnished serial examples of the metamorphoses by which the dense hard "blue-stone" is gradually altered into a soft, brilliantly coloured agatelike sandrock. (I have presented a somewhat extensive series of these to the British Museum (Natural History).)

PLIOCENE.—Beds of this age have been cut through, showing deposits of beautiful red-yellow loam, fifty feet thick, now lying at various altitudes, from a little above O.D. up to more than five hundred feet. These overlie a series correllatable with those of Ightdown. The underlying flint gravel is very much stained and of an orange-red colour, so familiar in East Anglia. The basement original sand is now indurated into a sandstone, requiring heavy steel tools to work it, in which were found worked flints. This, I think, is the first time worked flints have been found in a dense tertiary sandstone; naturally, the flints have undergone a great deal of alteration since they were chipped.

PLEISTOCENE.—The latest revelation has been made in the forming of battered-down lawn-tennis courts, upon the adjoining hillsides, and overlying the loam. The most southern court is cut out of chalky boulder marl, very white in colour. The associated boulders were often between two and three feet long, and consist of various gneisses, schists, granites, and numerous volcanic and metamorphic rocks; and sedimentary rocks foreign to the locality; and palæozoic and mesozoic fossils and rocks. The upper part of this big boulder drift was associated with immense worked flints, especially Wealden "flints," bulbed facets sometimes reaching one hundred square inches. The smaller implements are of well-known Mousterian types. In the overlying material came the orange-red-brown implements which I regard as of Aurignacian age. These later occur by thousands on certain hill-tops and valley shoulders in a quartzite drift full of glacially striated and faceted foreign rocks, originating in the destruction of just such glacial drift as is now revealed. Above these came quantities of the productions of the Hastings Kitchen Midden men. My esteemed colleague, Mr. Lamplugh, informs me that a similar drift has been reported to him from another locality. It now appears certain—if there be such a thing as a certainty—that glacial conditions reached even beyond our present shore line, and probably extended over the Great South river, as is shown by similar deposits near the French coast.

Zoological Nomenclature: Thirty-five Generic Names of Mammals.

THE following generic names of mammals (with the genotype in parentheses) have been submitted to the International Commission on Zoological Nomenclature for inclusion in the Official List of Generic Names.

The Secretary will delay final announcement of the votes on these names until January 1, 1925, in order to give to any zoologists who may desire the opportunity to express their opinions.

von Zeipel's Red Star near M 37.

THE very red star in the outlying regions of Messier 37 referred to in the Astronomical Column of NATURE of June 14, p. 870, was brought to our attention some years ago by Prof. v. Zeipel as an object of unusual interest.

Three polar comparison photographs in March and September 1921 gave a mean photovisual magnitude of 12·86, in exact agreement with v. Zeipel's result in *Astr. Nach.* 5288. Two polar comparisons made with ordinary plates on September 6 and 8, 1921, gave for the photographic brightness 17·75 and 17·95 respectively. The latter values are not very trustworthy, because the images were near the limiting magnitude of the plates; but the mean, 17·85, should be within 0·2 of the true photographic magnitude on the international scale.

The provisional colour index is, therefore, 5·0 mag. The ratio of the integrated intensity of the photovisual region of the star's spectrum (approximately λ5000 to λ6000) to that of the region to the violet of λ5200 is accordingly about 100 times the corresponding ratio for an Ao star.

A Biological Study of Radiation.

THE review of the second edition of our book, "Radium, X-rays, and the Living Cell," under the above title in NATURE of July 26 cannot pass without comment from us. One out of the two columns devoted to this review is a dissertation by the reviewer on the avoidance, by suitably directed regime and feeding, of the ills that fall to the lot of civilised man, including complaints such as cancer, dyspepsia, gastric and duodenal ulcer, gallstones, appendicitis, etc. We think that the natural inference of your readers will be that we have been writing on these matters; but we have neither written on this subject, nor do we subscribe to the opinions of the reviewer. Our efforts in producing the second edition of this book have, as in the first edition, been devoted to bringing together the chief experimental facts which have been ascertained of the effects which the rays from radium and X-rays have upon living organisms, and discussing very briefly any generalisations which may be possible on these facts.

Tropical Colonisation and the Future of Australia.[1]

By Prof. J. W. GREGORY, F.R.S.

IN North America the presence of the Negro has introduced problems of inscrutable perplexity; in South America a mixed race is in firm possession; in Africa as a whole the white man has no chance as a colonist; and in South Africa his future depends on some complex measure of segregation. In Asia, only in the north and north-west has the white man any prospect of permanent dominion. In contrast to these restrictions, in Australia the fundamental problem is the possibility of the occupation of the whole continent by the European race.

When the chief inrush of immigrants into Australia occurred after 1850, the belief was almost universal that the natural home of the white man was in the temperate zones and that the torrid zone must be left to the coloured races. That policy was accordingly adopted by Australia and pursued for fifty years. The tropical districts were left open, with varying limitations, to Asiatic immigration. Few Asiatics, however, took advantage of this opportunity, though large numbers were eager to enter the cities and settlements in the south, where the European had done the pioneer work. In the north the Asiatics were a hindrance, as they were too few to help materially, and they were sufficient to discourage the entrance of white artisans.

In 1901 Australia, on federation, found itself faced by two problems—the empty north which the open-to-Asia policy had not filled, and the disturbing effect of indentured coolies on white labour. The policy of excluding coloured people and working the northern plantations with white labour was declared to be a physical and physiological impossibility. In 1907, in opposition to this traditional view, I remarked ("Australasia," i. p. 15) that "medical authorities on tropical climates seem now, however, to be coming to the opinion that this view is a popular prejudice which does not rest on an adequate foundation." The evidence to that effect had been stated in a remarkable paper by Dr. L. W. Sambon, and endorsed by the late Sir Patrick Manson, and has been supported by the general trend of medical opinion during the past seventeen years.

The general distribution of mankind is in such close agreement with the rule that the white race has settled in the temperate regions and left the tropics to the coloured races, that any policy inconsistent with that arrangement must be prepared to encounter a strong prepossession to the contrary. Nevertheless, that rule is inconsistent with so many facts that it is not a safe basis for a national policy. In America, for example, the whole continent, except for the Eskimo in the north, was occupied by dark-coloured Mongolian tribes, in which, according to Flower and Lydekker ("Mammals," 1891, p. 752), "the colour of the skin, notwithstanding the enormous difference of the climate under which many members of the group exist, varies but little." The most northerly part of Europe is occupied by a coloured race, the Lapps. In Africa the darkness of the skin does not always vary in accordance with distance from the Equator.

[1] From the presidential address, "Inter-Racial Problems and White Colonisation in the Tropics," delivered to Section E (Geography) of the British Association at Toronto on August 7.

Supposed Unfavourable Factors in Tropical Climate.

(*a*) *Heat.*—The belief in the unsuitability of t tropics for the white man rests on several considerati Most importance is naturally attributed to the he as that is the essential difference between the tropi and other zones. Intense heat is regarded as injuri to people not protected by a dark skin. That vi overlooks the automatic process by which the livi body adjusts itself to temperatures even higher th occur in any climate on earth, and that would quic cook it, if dead. During some experiments by Charles Blagden in 1774, Sir Joseph Banks remain in a room for seven minutes at a temperature of 21 and Blagden subsequently stayed at the temperature 260°, while eggs were roasted hard and beefstea cooked in a few minutes. White men work in furna and bakeries at 600° F., and if they can survive su temperatures even for short spells, they should able to withstand the hottest climate on earth.

That heat is not the dangerous factor in the tropic obvious from the well-known fact that the hottest ar are often the healthiest. Agra is hotter and health than Bombay, and the summer heat of Colorado fiercer than that in the less healthy Mississippi Valle

(*b*) *Moist Heat.*—As dry heat affords no explanat of the high mortality of some tropical localities, app was made to moist heat, and to the combination of h and moisture marked by a high wet bulb temperatu At any temperature above blood heat the body cooled only by the evaporation of perspiration, wh does not take place in air saturated with moistu Hence in the Townsville experiments a man placed a room in which the wet bulb temperature rose fr 98° to 102°, fainted in forty minutes. In a hot local a dose of atropin, which suppresses perspiration, m be quickly fatal.

A wet bulb temperature higher than blood h would be fatal to men, white or black; but no eartl climate has such temperatures. It was at first s gested that the limit of human activity was the v bulb temperature of 73°, but there are well auther cated records of miners working for four-hour sp for months at the wet bulb temperature of 80° to in Hongkong, the Straits Settlements, Beaufort Borneo, and Ocean Island in the Pacific. At all th places people, both white and coloured, survive th conditions. Hence the limit has been gradually rai and it is recognised that men can withstand wet b temperatures of 85°, though the power of work un such conditions is necessarily greatly reduced. T highest wet bulb temperature mentioned in Dr. Grif Taylor's record at Port Darwin is 81°. The wet b data for North Australia are scanty; but there see no reason to expect that any considerable areas ha a more uncomfortable climate than Calcutta, to wh Dr. Taylor compares the worst localities of tropi Australia. Calcutta is one of the healthiest cities India, and has a large and vigorous European popu tion, many of whom spend there the whole year.

Moist heat is trying and must be considered in judg

cmates from the standard of comfort and personal eciency. The investigation of wet bulb temperatures, te significance of which was shown by Sir John Haldane, has been developed in reference to the textile ilustries by Dr. Leonard Hill and Dr. Boycott, to rning by Sir John Cadman, to the conditions of tpical Australia by the work of Prof. Osborne and is been illustrated by the ingenious climographs of I. G. Taylor; it has yielded results of high practical vlue. But the wet bulb isotherm does not delimit te areas where the white man may live and work, and des not really affect the question of white *versus* black conisation, as there does not seem to be any reason t believe that black men could withstand a higher vt bulb temperature than white men. In answer to a inquiry on this question, Sir John Haldane replied tat his impression on the contrary was that "white rn can usually stand more heat than black men," and h reported the information given him that in places lie the Red Sea the Clyde stokers stand the heat better tn the Lascars, "and, in fact, have constantly to cry the latter out and lay them on deck to cool."

(*c*) *Monotony in Temperature.*—Another temperature fctor that has been appealed to is that depressing eiability of temperature which occurs on some tropical csts. Excessive monotony in the weather is no dubt depressing, and temperature changes have a smulating beneficial effect. Extremes of cold and hat are still more inconvenient and trying, and a nderate equability is often advertised as an attractive fture in a climate. The equability of the oceanic cmate is recognised as most favourable for many condions of health. The areas over which extreme uiformity of temperature prevails throughout the year ar, however, so restricted that this factor does not aect the problem of tropical settlement as a whole. Vth the exception of low tropical islands, places with nnotonously equable climates are in positions whence ahange may be secured by a visit to some neighbouring hl country.

(*d*) *Actinic Rays.*—A fourth factor to which much iportance has been attached in connexion with the tpical climate is the effect of the chemical rays of the sn. Great importance was once attached to the pnicious influence of the ultra-violet chemical rays of te sun on persons not protected by a dark skin. Isidents in the tropics were therefore advised to line tir clothes with orange-coloured fabrics to shield tmselves from the chemically active rays. These vws reached their extreme in the writings of Surgeon-Mjor C. E. Woodruff in 1905, who held that the actinic rys of the sun are so inimical to the white man that ty inhibit his permanent settlement within 45° of the Euator. He therefore regarded the tip of Patagonia a the only area in the Southern Hemisphere fit for vite occupation. The temporary stagnancy of the ppulation of Australia after the droughts of 1900–1902 h regarded as evidence that the native-born white Astralian and delicate New Zealander were wasting aay through physical decay due to the enfeebling snshine, just as the health of American and European cldren was being ruined by the "daft" practice, as h called it, of flooding schoolrooms and nurseries with sreams of light. Woodruff's conclusions have naturally bn disregarded.

Any deleterious effects of the chemical rays of the sun may be avoided by the use of appropriate clothes, and physical considerations suggest that a black skin should afford less protection than a white skin. Any injury that may be wrought by powerful sunshine, according to Aron's work in the Philippines, is due to the heat rays at the red end of the spectrum and not to the chemical rays. The modern lauded system of heliotherapy is based on the belief that strong sunshine is a powerful curative agency.

(*e*) *Miscellaneous Factors.*—The four previously considered factors have the advantage that they can be readily understood and tested; but as they have failed to provide any basis for the unsuitability of the tropics for the white man, the appeal has been shifted to a complex of tropical influences, including a rise of body temperature, the lessened activity of lung and kidney, and nervous disturbances. Dirt and disease and carelessly prepared food are also mentioned, though they are due to human agencies. The physiological effects of the tropical climate in this indictment are contradicted by high authorities. The rise in body temperature is emphatically denied amongst others by Breinl and Young from observations in Queensland, and by Chamberlain on the basis of extensive observations on American soldiers in the Philippines. A slight rise may occur in passing from the temperate regions to the tropics, but it is soon recovered; and Shaklee reports from his experiments on monkeys at Manila that "the healthy white men may be readily acclimatised to the conditions named—that is, to the tropical climate at its worst." Shaklee adds that the most important factor in acclimatisation is diet.

The asserted ill-effects of the tropics on respiration appear to have no more solid basis. Prof. Osborne found at Melbourne that the rate of respiration was increased on the hottest days, and his observations agree with those of Chamberlain in Manila. So far from the tropical conditions being injurious to the kidneys, it is asserted, as by Dr. A. B. Balfour, that there is less trouble with that organ in tropical than in temperate climates. The apparently inconsistent observations on the action of the kidneys between various tropical localities and people may be explained by differences in diet.

The remaining charges against the tropical climate are insignificant, or not based on climatic elements, or are indefinite. Some of the alleged factors are trivial, such as the liability to various skin diseases owing to change in the skin reaction; for if the white man allows himself to be kept out of any country by such a cause he does not deserve to get in. The hygienic troubles due to association with an insanitary people are sometimes adduced; but they are not an element in climate and would not operate in a land reserved for white people. The remaining factors rest on ill-defined nervous ailments which are more likely to be due to domestic difficulties than to climate. These nervous troubles fall mainly on the women who have the strain of disciplining native servants into conformity with British ways. Nervous disorders are said to be worst in hot, dry, dusty regions which in the tropics are generally regarded as the most healthy, except to those whose constitutions require a moist atmosphere.

Medical opinion has gone far towards the general adoption of the conclusion that there is nothing in

climate to prohibit the white man from settling in the tropics.

As an example of a recent authoritative verdict may be quoted the report of a sub-committee appointed in 1914 by the Australian Medical Congress to investigate the medical aspects of tropical settlement. After extensive inquiries, the comparison of the blood of children born and bred in the tropics with those of the temperate regions, and other evidence, the sub-committee reported in 1920 as follows: "After mature consideration of these and other sources of information embodying the results of long and varied professional experience and observation in the Australian Tropics, the sub-committee is unable to find anything pointing to the existence of inherent or insuperable obstacles in the way of the permanent occupation of Tropical Australia by a healthy indigenous white race. They consider that the whole question of successful development and settlement of Tropical Australia by white races is fundamentally a question of applied public health in the modern sense. . . . They consider that the absence of semi-civilised coloured peoples in Northern Australia simplifies the problem very greatly."

Improvements by Public Sanitation.

The trend of medical opinion to the view that there is no physiological reason why the white race should not inhabit the tropics may lead to a change similar to that regarding some localities in the temperate zones, which were formerly regarded as death-traps and are now popular health resorts. The island of Walcheren, on the coast of one of the most densely peopled countries in Europe and only thirty miles from so fashionable a watering-place as Ostend, had, a century and a quarter ago, one of the most deadly climates in Europe. The largest army which had ever left the British islands landed there in 1809. Napoleon did not think it worth powder and shot. "Only keep them in check," was his order, "and the bad air and fevers peculiar to the country will soon destroy the army." Napoleon's judgment was justified. The force of 70,000 men disembarked on July 31 and August 1. By October 10, according to Sir Ranald Martin, 142 per thousand were dead of disease, and 587 per thousand were ill.

Algeria is now a trusted sanatorium. Yet disease annually swept away 7 per cent. of the French army that conquered it. Sir A. M. Tulloch remarked that if the French Government had realised the significance of that mortality "it would never have entered on the wild speculation of cultivating the soil of Africa by Europeans, nor have wasted a hundred millions sterling with no other result than the loss of 100,000 men, who have fallen victims to the climate of that country." The same change of view has taken place in reference to some tropical localities. The deadliness of the Spanish Main to our armies was described by Samuel Johnson. "The attack on Cartagena," he said, "is yet remembered, where the Spaniards from the ramparts saw their invaders destroyed by the hostility of the elements; poisoned by the air, and crippled by the dews; where every hour swept away battalions; and in the three days that passed between the descent and re-embarkation half an army perished. In the last war the Havanna was taken, at what expense is too well remembered. May my country be never cursed with such another conquest." Yet Havana, under American administration, has become one of the healthiest cities in the world.

Sir John Moore, when Governor of St. Lucia (179 wrote home that it is not the climate that kills, b mismanagement. His insight has been demonstrat in the same region. The French attempt to build t Panama Canal was defeated by disease. Discovery its nature enabled the late Surgeon-General Gorgas secure for the 10,000 men, women, and children in t canal construction camps, in spite of the high hum heat, as good health as they would have had in t United States. Gorgas claimed that the results Panama "will be generally received as a demonstrati that the white man can live and thrive in the tropic Gorgas realised that the results for the future are ev more momentous. He predicted that as "the amou of wealth which can be produced in the tropics fo given amount of labour is so much larger than th which can be produced in the temperate zone by same amount of labour, that the attraction for white man to emigrate to the tropics will be very gr when it is appreciated that he can be made safe as his health conditions at small expense. When great valleys of the Amazon and of the Congo occupied by a white population, more food will produced in these regions than is now produced in the rest of the inhabited world."

The Development of Tropical Australia.

The experience of colonisation in tropical Austra is limited to about seventy years; but it affords ground for the expectation that the ultimate effects the white race will be detrimental.

(*a*) *Vital Statistics in Queensland.*—In Queensla most of which is tropical, the death-rate is lower th in any European country and is lower than in mos extra-tropical Australia. In the six years 1915- according to the statistics in the Australian Year-b (No. 15, 1922, p. 99), the crude death-rate in Queensl was the lowest in the six Australian States for one y and fourth of the six States in three years, and the f in three; it was not once the highest. In the same years the infantile death-rate was lowest in Queensl in three years, and the second lowest in two oth According to the same authority, by Index of Morta (*i.e.* the death-rate in proportion to the ages of community), Queensland was in 1921 the second St in order of merit, being inferior only by 0·03 to N South Wales, the State most favoured in this respe

The physical vigour of the Queenslander is shown his athletic prowess, and by the low rejection-rate recruits from that State for the Citizen Army. longevity in Queensland may be judged by the exp ence of the life assurance offices. It has often b asserted that assurance rates show that tropical clima are unhealthy. Yet the chief actuary for the grea Australian assurance company, the Australian Mut Provident Society, reported to the Committee of Australian Medical Congress, "I have no hesitation saying that as far as we know at present there is need for life assurance offices to treat proponents w live in North Queensland differently from propone who live in other parts of Australia."

Physical and mental degeneration in a people liv

der unfavourable conditions would probably be most readily observed in the children. To use this clue I asked the Queensland Education Department whether its inspectors had noticed any unfavourable symptoms among the children in the most tropical of its northern schools. The Department replied that on the contrary its schools at Cairns and Cooktown, two of the most northern towns, are exceptionally efficient, and one of them is sometimes the leading school in the State.

(*b*) *Northern Territory.*—The great success of Queensland, although more than half the State is within the tropics, renders the more striking the failure of the adjacent Northern Territory of Australia, of which the records are disappointing. Agriculture has declined; the Government demonstration farms have been reduced to native reserves; the meat works have been closed; the population has fallen in numbers; and mining production has become insignificant. The present state of the Territory has been adduced as evidence of the futility of trying to develop a tropical land by white labour. Its failure was not, however, due to the White Australia policy, which was introduced after the failure was complete, but to geographical disadvantages not yet surmounted. The Territory, before 1901, was open to Asiatic immigration, but the hope that it would be adequately peopled from Asia was not fulfilled. Poorness of soil, unsuitable distribution of rainfall, and inaccessibility of position explain its backwardness. Great hopes are based on cotton, but its profitable cultivation appears dependent upon the establishment of a protected cotton manufacture in Australia, which would secure a market for the crop at a price that would pay for the high cost of picking. The remedy for the failure lies not in another attempt with Asiatics, but in the removal of the isolation of the Territory.

(*c*) *Queensland and the Sugar Industry.*—Queensland in contrast to the Northern Territory has made firm progress; the population has continued to increase; although at first coloured labour was introduced, the proportion of the Asiatic population in 1911 was only 1·7 per cent., and of the Polynesian only 0·29 per cent. The numbers of coloured labourers in Queensland were too small seriously to affect the population, but they were sufficient to be a constant irritant and source of uncertainty in the local labour market. This trouble led, in 1900, to the prohibition of indentured coolie labour throughout Australia. This decision was supported by the great majority of the Queensland people despite of the most emphatic warnings of disaster.

The Australian adoption of white labour for its sugar plantations has been the greatest contribution yet made to the practical solution of the problem whether the white man can do agricultural work in the tropics. The experiment shows that white labour can be employed successfully in such an ultra-tropical industry as sugar cultivation in even the ultra-tropical climate of the Queensland coastlands, provided the settlers are protected from infectious disease and from the competition of people with lower standards of life.

Drawbacks of the Tropical Climate.

The conclusion that white settlement of the tropics is possible should not lead to the drawbacks of a tropical climate being overlooked. The conditions where the wet bulb temperatures are high are uncomfortable and unfavourable to mental and physical activity. People who are not keenly interested in their work should avoid the tropics. Ellsworth Huntington in a valuable series of works has directed attention to many facts which show the dependence of Western civilisation on the stimulating nature of the temperate climate, for the frequent changes in temperature and wind are conducive to alertness and general efficiency.

The enervating effect of the tropical climate is no doubt counterbalanced by various compensations. Man needs less in food, fuel, clothing, and housing, while the same amount of exertion will produce a more luxuriant and valuable crop. The supremely fertile tropical regions have, however, usually a hot muggy climate, which is not attractive to Europeans while areas with less trying conditions are available. Northern Australia, even if it were not hampered by a high proportion of poor land, would naturally develop slowly, just as in Canada the Northern Territory and the rocky backwoods have lagged behind the St. Lawrence basin and the rich-soiled western plains.

Conclusion.

The conclusion that the white man is not physiologically disqualified from manual labour in the tropics and may colonise any part of Australia simplifies interracial problems, as it provides an additional outlet and spacious home for the European race.

The preceding survey of the position where the three main races meet in intimate association indicates that the world will have a happier and brighter future if it can avoid the co-residence in mass of members of the different primary divisions of mankind. Individual association and contact should secure for each race the benefit of the intellectual, artistic, and moral talents of the others; while industrial co-operation should aid each nation to make the best use of the land in its care.

The world has reached its present position by the help of each of its three great races, and it still needs the special qualities of each of them. The contemplative Asiatic founded all the chief religions, the ethical basis of civilisation. The artistic Negro probably gave the world the gift of iron, the material basis of civilisation. The administrative genius of the European race has organised the brain power of the world to its most original and constructive efforts. The affectionate, emotional Negro, the docile, diligent Asiatic, and the inventive, enterprising European do not, however, work at their best when associated in mass. That association is attended with serious difficulties; for race amalgamation, which is the natural sequel, is abhorrent to many nations, and the intermarriage of widely different breeds, according to many authorities, produces inferior offspring. The policy of co-residence with racial integrity has failed to secure harmonious progress in North America and South Africa. The development of the best qualities of the three races requires their separate existence as a whole, with opportunities for individual association and co-operation.

In view of the inter-racial difficulties that have developed wherever the races are intermingled, Australia will throw away a unique opportunity if it fails to make a patient effort to secure the whole continent as the home of the white race.

A Philosopher on Relativity.

By Sir OLIVER LODGE, F.R.S.

AT the twenty-third annual meeting of the Eastern Division of the American Philosophical Association, held at Brown University, Providence, R.I., in December 1923, a presidential address on "The Einstein Theory and a Possible Alternative" was delivered by Prof. William Pepperell Montague, professor of philosophy in the Columbia University of New York. In this address Prof. Montague shows himself to be a philosopher rather especially interested in physics; and he claims the advantage of having discussed certain aspects of the subject with Prof. Bergen Davis and other members of the physics department at Columbia. He reviews and criticises parts of the Einstein theory in a lively manner, thereby arousing interest among philosophers; and his contentions are deserving of notice.

Apparently Prof. Montague raises no objection to Einstein's General Theory, so far as it deals with matter and gravitation, and so far as it replaces the idea of force by the idea of space-curvature. He seems to consider these apparently diverse ideas as only different methods of expressing the same thing; much as you might say that it does not matter whether you represent an ellipse by drawing it, or by writing $x^2/a^2+y^2/b^2=1$. Both modes of expression represent the same thing. Some might hold that a picture is a nearer approach to reality than a formula, but both call up relevant ideas in the mind. Moreover, a picture,—which regarded from a strict point of view is millions of molecules of one substance superposed upon billions of another,—must depend helplessly on the human mind for recognising in it any of the properties of an ellipse!—must, in fact, depend just as much on mind for its interpretation as does the algebraic convention. After all, as regards precision of measurement, the mathematical rather than the pictorial presentation is the more explicit and accurate of the two.

I must make it clear that Prof. Montague expresses appreciation of pure mathematics and feels no philosophical objection to those more striking and revolutionary ideas of Einstein which were borrowed from the pure mathematicians. In the geometrical way of regarding matter and force, the infinite finiteness of the universe, the representation of impenetrable specks of matter as impassable distortions of space,—in all this Prof. Montague rather rejoices; as the following extracts will show:

". . . bodies moving with accelerated velocities are subject to forces, hence the later Einstein theory consists, first, of a new though Cliffordian conception of the nature of *force*; and, second (growing out of that), of a new though Riemannian conception of the *universe itself*, as a domain at once boundless and finite. . . .

"Some will undoubtedly feel stifled and penned in at the thought that if they were to travel in a 'straight' line for only a few septillions of miles they would find themselves on the way home without ever having turned around. Others will find the new Riemannian hyper-sphere large enough for all practical purposes; and they will delight in the possibility of relating in some curious way the curvature or size of the universe as a whole to the dimensions of its minimum elements."

Prof. Montague does not think that the hyp geometrical conceptions of reality need be upset what he urges as failure in the simpler basis on wh the original doctrines of relativity were founded doctrines admittedly not so well established by act *ad hoc* observation of predicted results as those of t more general theory have been.

"It is not, I think, too inaccurate to say that wh the Special Theory reduces geometry to physics a is offensively destructive and phenomenalistic in conception of the world, the General Theory redu physics to geometry and its tone and temper rationalistic and constructive. The muddy prose Hume and Mach gives place to the clear poetry Riemann and Clifford."

Prof. Montague goes on to pay a tribute to the l Prof. Clifford, with which, as an old student and jun friend of that remarkable genius, I cannot but sy pathise:

"It was Clifford, working under the inspiration the new geometry of Riemann, who, I think, fi suggested that matter could be conceived as a n Euclidian wrinkle in space. . . . It is pleasant think that Clifford, whose mind was of such r beauty and who in his appreciation of spiritual val possessed what the musicians call a sense for absol pitch, should have been the first to hold a concept which now seems destined to have most far-reach consequences."

So it turns out that Prof. Montague's criticisms directed, not at the more recondite parts of the subj so finely developed and expounded by Eddington, l at its foundations as ordinarily expressed. His m objection seems to be to the Larmor-Lorentzian l for the composition of velocities, and to the absol constancy of the velocity of light as supposed to measured by different observers. He objects also this velocity being regarded as a maximum veloc which cannot be exceeded. His view is that ligh not really emitted and abandoned to a station ether, as a water splash is abandoned by a ship, l that light is continually associated with the lines field of force belonging to and moving with the sou —somewhat after Faraday's idea of ray vibratio an idea which, in modified form, has obtained weig support of late, and about which it is best not to dogmatic.

There has been a conspicuous tendency, of late, revolt against the simplicity of the undulatory the Something more than that is evidently wanted. A incidentally I may mention that Prof. Benedicks, the Metallographic Institute of Stockholm, has writ an immediately forthcoming small book called "Sp and Time," in which he supports some modificat of the emission theory. With a corpuscular the in empty space, the Michelson-Morley experim would raise no difficulty at all, and probably wo never have been performed; for the velocity of li would depend on the motion of the source, and eve thing would be simple. A similar simplicity is ain at by Prof. Montague. He does not indeed propos corpuscular theory—he sees difficulties in that,—l

is well aware that what he does suggest is quite ien, and indeed contrary, to the early parts of the instein theory. He adduces therefore simple imagin- y experiments, akin to those so often appealed to philosophic relativists, by which he thinks the instein view might be disproved. He realises the fficulty of doing anything effective with only two gnalling observers, who must be dependent on in- nclusive to-and-fro journeys, so he arranges a iangular duel, with a third observer, or rather gnaller, equidistant from the other two.

Let there be two observers on the same parallel of titude, with perfect signalling appliances and stop- atches, which, however they are affected by the tation of the earth, must at least go at the same rate ; nd let there be a third signaller at the north pole, ho by symmetry is able to establish simultaneity etween the other two. At the word "Go!" from he pole, the two on the equator signal to each other, nd time the interval between sending and receiving. rof. Montague claims that, on the ordinary wave heory, and as he mistakenly seems to think on the instein theory, the one travelling to meet the signal hould get it sooner than the one whom it has to vertake. For, as he says, even waves take less time travel less distance,—. . . "even Einsteinian light avels a shorter distance in less time than it does a nger distance."

On the other hand, on a corpuscular theory there ould be no observable difference, because the increased eed of the corpuscles from an ordinary source would mpensate for the recession of their recipient. So oth Prof. Montague and Prof. Eddington would, I resume, expect a negative result ; and the experiment ould not discriminate between them. Unless, indeed, gave a positive result, to the chagrin of both, and the iumph of a common-sense view based on the behaviour f ordinary waves.[1]

It will be observed, however, that Prof. Montague has bandoned translation, as hopeless for his purpose, and as utilised rotation ; and about rotation there has lways been something with a tinge of the absolute bout it, even in relativity doctrine. But whether it is ecessary to make this admission, in order to safeguard positive result from Prof. Montague's imaginary xperiment, is very doubtful. His own attitude is ostile to waves in a stationary ether, as well as to the ss intelligible doctrine that every observer, at all imes, must measure the same velocity for light; he oes not actually sustain or mention a corpuscular heory, as Prof. Benedicks does,—and as apparently the Swiss genius Ritz did,—but his postulated entanglement f the waves with the field of the source comes to omewhat the same thing.

Prof. Montague goes on to attack the composition of elocities in a more direct manner, and likewise ridicules everal curiosities of time measurement, including ueer tales by rapid travellers with return tickets, ited from Eddington and Weyl ; but concerning the ypothetical slowing down of physiological processes y motion, and other humorous interpretations of ertain equations, I am not myself seriously sym- pathetic enough to justify my trying to sustain them against criticism.

Incidentally I note that he has a long footnote in which, by means of to-and-fro north and south signalling compared with the result of similar east and west signalling, he claims that we might distinguish between Einstein and Lorentz,—whatever that may mean. It looks as if he thought that Einstein discarded the β factor representing the FitzGerald-Lorentz Contraction (introduced by Larmor in 1900, "Æther and Matter," p. 173 *et seq.*, and vigorously used by Einstein), while Lorentz admitted it. Either I misunderstand him here, or he makes a mistake.

The alternative which Prof. Montague seriously proposes to the relativity treatment of light is not the corpuscular theory,—for, as he says, "light is in almost all respects wave-like rather than corpuscular"—but it is this,

". . . that the medium or carrier of light waves is not a doubtfully existent ether-substance, but the certainly existent field of force which each electron and proton carries with it."

He thus desires to abolish a stationary ether, as Einstein does not, and claims that because an electric field is centred on its charged particle, it follows that when a charged particle moves, its field must move with it.

"The velocity *in* the field will be constant and absolute, but the velocity *of* the field has to be added to it."

Thus he tries to combine the advantages of the wave and emission theories in this respect. But the full treatment is not so simple ; a great deal is known about the way in which a field moves, and he would find himself immersed in plenty of complexities, unless he discarded electromagnetic theory altogether.

Finally Prof. Montague proposes an experiment to test his crucial assumption, namely, that the velocity of light is affected by the motion of the source, and is not independent of it as it would be in a stationary ether and as it is in Einstein's theory. His proposed experiment depends on rotation, again ; and, to summarise it briefly, it employs the idea that light from the sun's advancing limb ought to come to us quicker than from the receding limb. His proposed rotator is not the sun, however, but a mechanical cylinder, sphere, or disk, projecting light from opposite points of its circumference, through a couple of narrow slits or tunnels, on to a moving sheet of sensitive paper. The slits or narrow tunnels are carried by a pair of drums, which are separated by a considerable distance and are revolving about an axis at right angles to the main axis and parallel to the path of the two beams of light. (He makes these drums revolve in opposite senses, but that is surely a mistake or a needless complication.) It follows that if they are revolving quickly enough, the light may be unable to get through both slits, because of the time taken in the journey between them, and he claims that with increasing speed the fading of the spot from one beam should precede the fading of the other. His experiment therefore is really a Fizeau-like experiment to measure the velocity of light, or rather to compare the velocities from two oppositely moving sources without the use of a mirror or any return journey: the fading and disappearance of the traces on the photographic film at a certain

[1] May I direct attention to a clear pre-relativity description of all this lass of problem, in an old volume of NATURE for 1892 (vol. 46, pp. 497-502, nd also on pp. 164 and 165 ; the latter with a misprint of θ for ϵ in two laces).

speed of rotation being looked for, and the times of fading compared. But presumably any mode of determining the velocity of light would serve: the essence of the experiment is not the mechanical details, which are crude, but the suggestion that it is possible to find a difference in the velocity of light according as it comes from the approaching part of a rotating wheel or from the receding part.

Well, that is a definite suggestion for experiment, if any one really thinks it likely (as I do not) that the velocity of light depends on the motion of the source: though it would seem as if measuring the velocity of light from an approaching and receding star would be more likely to decide the question. At any rate, the difficulties encountered by employing a non-terrestrial source would be of another order. Prof. Montague fears, however, that a final entanglement of the light in the fields of atmospheric matter might interfere with a correct determination of velocity from an astronomical source. It might also be argued that the known Doppler effect, depending on stellar advance and recession, gives a relative frequency accurately calculable on the basis of a constant velocity for light, and that to supplement this by the peculiarities of a projectile kind of light would be merely perturbing. To this he would doubtless reply that a fair and square initial consideration of light as projected from its source will give the Doppler effect and explain the M.M. result with perfect ease. He might also claim, perhaps, that his variety of ray-wave would evade the usual Foucault objection to emission theories, and might give the Fizeau result in dense substances as well. These things are not elaborated in his paper.

But now—seeking what can be politely said in support of any of his contentions—it must be admitted, I think, that the relativity explanation of the Doppler effect can be made to look as if it had a weak point. Algebraically it comes out right, of course, but it has too much the air of the ordinary explanation, which attributes an obvious meaning to $c \pm v$. The ordinary explanation, for an observer approaching a source, is simply that the observed frequency increases in the ratio

$$\frac{n}{n_0} = \frac{c+v}{c}$$

by simple composition of velocities: which is still Professor Montague's, and used to be everybody's, argument. But, with the relativity law for compounding velocities, deduced from Larmor's transformation, this so described ratio would be unity, and there would be no Doppler effect at all if it had to depend on an apparently changed speed of arrival of the waves. Relativity, however, does not attempt to proceed by compounding velocities for the purpose of explaining the Doppler effect: it knows that c cannot be added to or subtracted from, by anything a source or an observer can do; so it simply applies the Larmor-Lorentz transformation to the space and time periodicities of wave motion, and deduces algebraically

$$\frac{n}{n_0} = \sqrt{\left(\frac{c+v}{c-v}\right)}.$$

Neglecting v^2/c^2 this has the same value as the ordinary expression above, and no experiment yet made can discriminate between them. But am I wrong in imagining that a relativist would dislike writing it in that form and would prefer the expression

$$\sqrt{\left(\frac{1+v/c}{1-v/c}\right)}?$$

For this, though identical, conveys no inappropriate suggestion of compounded velocities.

In conclusion, it is always satisfactory when controversialists can get up against a question of fact. Stripping it to bare bones, we may put these two questions:

(1) Does the velocity of light really depend on the speed of its source?

Wave theory, Einstein theory, ether theory, all say "no." Corpuscular theory answers "yes": and Prof. Montague's adopted conception of a ray vibration also, in his opinion (but as I think doubtfully) answers "yes."

(2) Does the measured or apparent velocity of light depend on the motion of an observer?

Corpuscular theory, and Prof. Montague's theory reply, "Yes if the source is stationary," "No if the source is moving with the observer." Ordinary wave theory would say "Yes in any case," for what the source is doing does not matter; that can only affect wave-length, not speed. Einstein's theory would loudly say "No in any case": for if one could discriminate between motion of observer and motion of source, relativity as commonly stated would be upset and attention to a stationary ether would be made inevitable. Experiment so far has declined to answer; for a to-and-fro journey involves squares and can be dodged. So then at present we have no discriminating reply, unless an answer in favour of Einstein is to be taken as implied by the general consistency and sufficiency of his theoretical results both old and new.

One who is impressed with the mysterious way in which the Larmor-Lorentz transformation thoroughly formulates all known results without any trouble or hesitation, and yet who is not helped thereby to form a clear physical conception of the process, might urge that to clinch matters an experiment is desirable which should aim at determining $c \pm v$; when v is the speed not of source, but of observer. That is, an experiment is wanted which would measure the speed of an observer relatively to light, and therefore relatively to a stationary luminiferous medium. Direct determination of the velocity of light at different seasons of the year, by any method, would at first sight seem able to settle this question, provided an accuracy greater than one in ten thousand could be attained.

But consider this further. A fixed space-interval and a time-keeper constitute the real observer: the FitzGerald contraction does not depend on whether motion is positive or negative, nor does direction of motion affect the rate of a clock. Hence if the experiment is made now and six months hence, x/t will equal x'/t', and no difference in the speed c will be perceived. That seems right from one point of view; and yet physically, waves *ought* to travel down an ether stream quicker than up, unless group velocity has something objectionable to say.

To sum up the position, still in an interrogative

[2] Because $\frac{x'}{t'} = \frac{x/t - u}{1 - ux/c^2t}$, which equals c if $x/t = c$, and not otherwise.

nner without dogmatism :—change of frequency epends solely on relative motion of source and server: combined motion of both through a medium es not affect frequency on any theory, so long as e motion is steady. Ordinary aberration is wholly d solely caused by motion of observer relative to th of ray. Is observed velocity of light depend- t on motion of observer, too? The strength of the ativity position is that no way of performing the experiment is likely to give a positive result, unless truly relative motion is introduced, as by mounting the whole receiver on the end of a revolving arm; and questionably even then. The strength of the ether position is that a relative ether stream past fixed "stations," though undemonstrated, is at least not negatived by this or any other experiment, and may therefore nevertheless be a reality. A philosopher may be able to explain what "reality" means.

Obituary.

DR. ROBERT KIDSTON, F.R.S.

BY the unexpected death of Robert Kidston on July 13, palæobotany suffers an irreparable loss. Dr. idston was still at the height of his activity, and had obably never been busier in his life than when the d came. He was then in South Wales, engaged on s fossil investigations. Equally distinguished in stematic and structural palæobotany, Kidston was e veteran leader in his science, worthy to rank with e great continental masters, such as Zeiller, Grand'- ury, and Nathorst, who had already passed away.

Robert Kidston was born at Bishopston House, enfrewshire, on June 29, 1852. The family removed ortly afterwards to Stirling, where Kidston's life as spent. As a young man Kidston went into siness in a bank, but his strong bent for natural story soon turned him towards scientific pursuits. bout 1878 he attended botanical classes in the niversity of Edinburgh. He was then, and remained roughout life, a keen field botanist.

Kidston soon became interested in fossil plants, and is work met with early recognition, for, from 1880 nwards, the plant-remains collected by the Geological urvey of Scotland were referred to him. This gave im his first great opportunity.

In Kidston's work as a fossil-botanist two periods ay be distinguished. From the beginning up to 904 he was predominantly a floristic and strati- raphical palæobotanist, and so indeed he continued o be, but from 1904 onwards he further took a leading art in morphological and structural investigation, and xpressed himself with a wise authority on the great uestions of affinity and descent. His work in every eld was remarkable for that sound judgment which as so generally characterised the best systematists.

From about 1880 a constant succession of papers n fossil plants was maintained; only a very few can e mentioned here. In 1886 Kidston was entrusted ith the duty of preparing a catalogue of the Palæozoic lants preserved in the British Museum, a valuable ork of reference in its time. Thus he was already ecognised as our leading systematist in Palæozoic otany.

Kidston always took a special interest in the ructification of ferns and fern-like plants. A paper ublished in 1887, "On the Fructification of some erns from the Carboniferous Formation," proved to e of exceptional importance, for various reproductive rgans described belonged, as Kidston afterwards howed, to the group of the Pteridosperms. Thus, in he case of *Neuropteris heterophylla*, of which he after- vards discovered the seed, the fructification described n 1887 turned out to be the male form.

The memoir on Lepidophloios (1892) is the leading monograph on that genus of fossil Lycopods. A paper on the various divisions of the Carboniferous rocks as determined by their fossil flora (1893) is a valuable contribution to the geology of that period. Two important memoirs on the fossil flora of the Yorkshire coal-field, on which he had already published a number of reports, appeared in 1896 and 1897. The second is of remarkable interest, as containing the first complete description of the cones of Sigillaria, and thus finally establishing the true nature of that long-disputed genus.

A general summary of the flora of the Carboniferous Period appeared in 1901–1902. This was written at a transitional time, when botanists had recognised the Cycadofilices as a class, but were still ignorant of their reproduction. Kidston's remarks do justice to the position at that date.

The second and more brilliant period of Kidston's work opens with his important paper on the fructification of *Neuropteris heterophylla* (1904). He was the first to demonstrate, by direct proof of continuity, that a fern-like plant of the Coal Age bore seeds. Previous evidence (only slightly antedating Kidston's discovery), however convincing, had been indirect. Kidston, in fact, was a pioneer in this field. A year later (1905) he published a preliminary note on Microsporangia in connexion with the foliage of Lyginodendron and was thus the first to identify the male organs of a "seed-fern." This was followed up in 1905 by his great memoir on the microsporangia of the Pteridospermeæ, a truly admirable work, showing a rare soundness of judgment in discussing the affinities of the newly discovered group.

A purely anatomical memoir on the internal structure of *Sigillaria elegans* (1908) was the first full and illustrated account of the structure of a ribbed Sigillaria. The work was extended to other species a year later.

Other papers on structural subjects dealt with new species of Dineuron and Botryopteris (early ferns) and with a new Lepidodendron from Pettycur, all of Lower Carboniferous age. Kidston had a special predilection for Lower Carboniferous plants, and was among the first to grasp the full importance of this fine flora.

One of Kidston's later memoirs on the fossil flora of the Staffordshire Coal-Fields (1914) includes a number of important discoveries, the most striking being perhaps the pollen-bearing organ of a new Neuropteris, very different from that of *N. heterophylla*.

The mere glance we have taken at a few outstanding papers may serve to show how Kidston's work illuminated every side of Palæozoic botany. His work was fully appreciated on the Continent and was by no

means confined to his own country. In 1911 appeared a fine volume on "Les Végétaux houillers recueillis dans le Hainaut Belge" containing various new genera and species. Another foreign work was his joint book with Dr. Jongmans on the Calamites of Western Europe, published by the Dutch Government. This is a huge monograph; the Atlas published in 1915 contains 158 fine plates. So far as the writer is aware, only a portion of the text has appeared.

It remains to notice briefly some of Kidston's work in conjunction with other botanists. One of his most valued colleagues was the late Prof. D. T. Gwynne-Vaughan, whose early death was so severe a loss to botany. Their work on the fossil Osmundaceæ, in five parts, ranging from 1907 to 1914, is a palæobotanical classic, tracing back the history of the Royal ferns from the Tertiary to the Permian. An admirable photograph is extant, showing the two collaborators at work together on this investigation. Other papers with Gwynne-Vaughan were on a Tempskya from Russia, by far the best account up to that time of this peculiar type of fern-stem, and on a Lower Carboniferous fossil, *Stenomyelon tuedianum*, discovered by Kidston. This is a model of anatomical work, concise, clear, and exhaustive.

Kidston's work in conjunction with Prof. W. H. Lang, on the Old Red Sandstone plants of the Rhynie Chert-bed (five memoirs, 1917–1921), was the most important of all, for it demonstrated, in full detail, the structure of the oldest land-plants of which we have any certain knowledge. Never was a great discovery more completely and wisely expounded. The simple plants of Rhynie, thanks to Kidston and Lang's researches, now form the basis of evolutionary work on the plant kingdom.

Other joint memoirs by the same authors were on Hicklingia, a new genus of Early Devonian Plants (1923), and on *Palæopitys Milleri* (1923), the famous but long neglected "cone-bearing tree" of Hugh Miller. The authors worked out the structure fully, but reserved judgment on the affinities of the plant, which is certainly of astonishingly high organisation for an Early Devonian horizon.

Kidston, at the time of his death, was engaged on what, from a floristic point of view, was to have been the greatest work of his career. This was nothing less than the full description and illustration of all the Carboniferous plants of Great Britain. The series, published by the Geological Survey, was planned to consist of ten memoirs but would, no doubt, have run to more. Four memoirs have been actually published, illustrated by 91 fine plates. They only embrace a portion of the ferns and fern-like plants. The systematic descriptions are illuminated by admirable observations on broader questions of affinity. It is understood that two more parts are sufficiently advanced for publication, and it is earnestly to be hoped that this magnificent work, a credit alike to the author and to the Department which undertook it, may eventually be brought to completion.

Kidston, among his other accomplishments, was a highly skilled photographer and was thus enabled to illustrate his own works, both systematic and anatomical, in a manner which adds immensely to their value and beauty. In all his writings Kidston showed himself a most fair and generous critic. His splendid colle tions both of impressions and sections were alwa available for the use of his scientific colleagues. T present writer, in particular, can testify how mu he owes to the constant and generous help of his o friend. D. H. S.

Prof. Alois Mrázek.

On November 26, 1923, died Dr. Mrázek, profess of zoology in the Charles' (Bohemian) University Prague. He was born in 1868 in Příbram, and origi ally worked under A. Frič in the patriotic study of t fauna, the aim of which was to increase the knowled of Bohemian fauna and the extension of the sing genera. Later on, under the influence of his secon teacher, Prof. Vejdovský, he devoted his study typical problems of the period of classical morpholo and cytology. He did not limit himself only to t discovery and description of new genera, but he w also interested in the problems, which are typical f the area, of the classical morphology and cytology.

Mrázek directed his study chiefly to the Crustac and Copepoda, especially to the hermaphroditism the first and the numerous anatomical details of t antennæ of the second, and the exactness of his wor became known in foreign countries, from whic valuable material was entrusted to him for researc He found cystercoids in copepods, and their stud brought him to that of the complicated cycles of t evolution of helminthes, and so he became a co-edit of the *Journal of Parasitology* and a member of t Helminthological Society of Washington. He i vestigated also the Sporozoa, Planariæ, Oligochæt and studied very deeply the life of ants, all work great exactitude, and discovered fresh-water Neme tines in Bohemia, as well as the only representative subtropical Temnocephalids in the Lake of Scutar His beautiful drawings appear frequently in the larg works on cytology. Mrázek was a modern zoologi who was a master of the problems of his time, not one-sided systematist or a mere morphologist. H work touched also problems of variability, heredity acquired characters, regeneration, and he devoted good deal of his time to the study of the relation between the organism and the medium in which lives, to ecology.

Mrázek was a splendid teacher, full of sacrific especially in laboratory work. He published a seri of popular lectures on the theory of evolution, and tran lated Romanes' work, "Darwin and after Darwin." He founded a small but pretty aquarium in his institut which is visited by thousands of students and othe people. While still living, he presented to his institut his rich private library and all his instruments, et He was a member of the Bohemian Academy of Scienc and of the Royal Society of Bohemia. His death is great loss to our University.

Bohuslav Brauner.

We much regret to announce the death of Pro P. Natorp, emeritus professor of philosophy in th University of Marburg, author of "The Logic Foundations of the Exact Sciences," and leader o the neo-Kantian school, aged seventy.

Current Topics and Events.

THE East African Parliamentary Commission has started on its long journey, a journey fraught with great and manifold possibilities. If any assurance was needed that scientific matters would receive their fair share of attention, it is to be found in the fact that Major A. G. Church, a member of the Medical Research Council, is one of the Commissioners. No such assurance is, however, required, for Mr. W. Ormsby-Gore, the chairman, is fully alive to the important part which scientific knowledge plays, and must continue to play, in the development of our tropical possessions. He has not forgotten the lessons learned in the West Indies, and realises that many of the same problems will be found in East Africa, together with others peculiar to what was once called the Dark Continent. Indeed, he and those with him are well aware that it is in the main owing to the triumphs of science that the old opprobrious title is no longer wholly applicable, but they are also persuaded that much more light requires to be shed on many difficult questions before the darkness which at present enshrouds them can be fully dispelled. Human, animal, and plant diseases will all engage their attention. All three are closely linked, perhaps more closely linked in Africa than anywhere else in the world. Examples come readily to mind: there is human sleeping sickness and animal trypanosomiasis, which the Commissioners will find in every territory they visit, and one thinks also of the calamity of a heavy aphis infection of millet and the famine which may follow it, and of the desolation which locusts leave in their track and the dire effects of their inroad upon both man and beast.

WHILE certain human diseases—as, for example, sleeping sickness, malaria, tuberculosis, leprosy, dysentery, yaws, the venereal complaints, and so forth—will be found common to all the countries in which the East African Parliamentary Commission will prosecute its inquiries, there are others to which the Commissioners' attention will be particularly directed in certain localities. In Northern Rhodesia there have been many cases of splenic abscess amongst natives, an obscure condition requiring research; plague merits special attention in Nyasaland and Kenya Colony; while in Uganda cerebro-spinal fever causes many deaths amongst natives. Again, some of the general diseases are more serious in certain territories than in others. Yaws is a crippling force in Kenya, syphilis a devastating disaster in Uganda. All these questions will require consideration, as will those of native hygiene generally, a subject intimately bound up with housing conditions and therefore with technical education. Veterinary problems abound, and in connexion with them and with many plant diseases the necessity for entomological research will be apparent, as indeed is also the case with respect to human pathology. It will be seen that on the scientific side alone there will be plenty to engage the Commission's attention. It cannot deal with details, but if it grasps some of the great underlying principles and speaks eventually with authority as to the necessity of increased facilities for education and research and for coping with disease and death, it will not have travelled and laboured in vain.

THE Government has decided to proceed at once with certain preliminary investigations in order to ascertain the feasibility of the scheme for using the tidal power of the River Severn for the production of electrical power by the erection of a barrage across the river. Lord Parmoor, to whose scientific department (the Department of Scientific and Industrial Research) the work has been entrusted, has already made arrangements to put it in hand. The Lord President of the Council has appointed the following Committee to supervise and direct the work:—Mr. G. S. Albright (chairman), Prof. A. H. Gibson, Mr. G. W. Lamplugh, Mr. Maurice Wilson, and Dr. J. S. Flett. The feasibility of the Severn scheme turns upon the possibility of finding satisfactory foundations for a barrage. Accordingly the first stage of the investigation will involve:—(*a*) The study by the Geological Survey of the stratigraphical formations in the neighbourhood of the sites suggested for the erection of the barrage; (*b*) taking preliminary soundings with the view of determining the contour of the river-bed at the sites; and (*c*) preliminary measurements of the flow of water at different states of the tide. Meanwhile, two eminent consulting engineers, Sir Maurice Fitzmaurice and Sir John Purser Griffith, have been invited by the Lord President to submit a joint report before the end of this year as to the possibility of constructing a barrage on one or more of the sites suggested on the assumption that safe foundations exist. The data which will be provided as a result of the geological and hydrographical investigations will be placed at their disposal. The staff of the Geological Survey has already begun the inquiry, and a report will probably be ready for submission to the Committee before the end of September.

BETWEEN 11 and 12 P.M. on August 22, a slight earthquake (intensity 4, Rossi-Forel scale), which lasted about six seconds, and was followed by another after an interval of about a minute, was felt in Inverness-shire, at Gairlochy, Spean Bridge and Roy Bridge, all within a few miles of the Great Glen fault. This fault, which runs from Tarbat Ness and crosses Scotland along the line of the Great Glen, has given rise to earthquakes in several parts of its course. Shocks are strongest and most frequent in the section between Inverness and the north-east end of Loch Ness, the last series being those of 1901. From 1870 to 1906, at least seven shocks occurred in the neighbourhood of Fort William, and it is possible that the strong Oban earthquakes of 1880 and 1907, as well as other slighter movements farther to the south-west, were connected with this fault. But, so far as known, this is the first time that an earthquake has originated near the south-west end of Loch Lochy

We are interested to learn that Mr. Joseph F. Rock, head of the National Geographic Society's expedition into Yunnan, S.W. Szechuan and S.E. Tibet, has recently returned to the United States after eighteen months in the field. He reports the finding of aboriginal tribes in China practising religious ceremonies which existed before Buddhism was introduced into either China or Tibet. He also brought back important plant and bird collections, the herbarium specimens numbering some 12,000 specimens. The plants were collected in the extreme north-west of Yunnan, Tsarong, south-eastern Tibet, the independent Lama Kingdom of Mili and also in eastern Yunnan. The birds collected number about 1600, and are from regions where few collections had previously been made. The collection contains land and water birds, and in addition a few hundred mammals. The birds and mammals will be presented to the Smithsonian Institution. Chestnuts of apparently immune species were found which may prove of value in the United States where the chestnut disease has wrought such havoc. Mr. Rock's chestnut introduction should prove of great interest to the tanning industry in the United States, which has depended upon chestnut to a great extent and has recently faced the possibility of this supply being destroyed through the ravages of blight. A fine set of firs, spruces, hemlocks, pines and junipers were also brought back. A large collection of rhododendron seeds was made, amounting, it is stated, to 493 kinds, and specimens of many of the rhododendrons as well as seeds of these and of Alpine plants have been sent to Kew and to Edinburgh.

In his presidential address to the Society for Psychical Research, just published, Mr. J. G. Piddington emphasised the difference between the certainty of astronomical predictions and the certainty of the psychical phenomena studied by the Society by saying that the Astronomer Royal, if he wished, could safely wager 5000*l.* to 1*l.* that an eclipse would take place at a certain time, whereas no such wager would be safe in, say, a case of alleged telepathy or clairvoyance. The comparative immunity from such uncertainty enjoyed by most men of science, he said, might actually disqualify them from being the best judges of the Society's work. The best policy would be to aim at convincing the average educated person. One of the difficulties lay in the fact that every science tended to become more and more complex, and those members of the Society who did not keep pace with the development of their methods were inclined to lose interest in their proceedings. Thus the latest automatic writings of some of their members were a sort of elaborate and extensive mosaic, a galaxy of cross-correspondences. In Mr. Piddington's opinion, this greater complexity arose from *someone's* intelligent design, though he would not venture to trace the intelligence which was deliberately complicating some of the phenomena investigated by the Society. The greater danger was a wave of credulity and superstition. The cause of psychical research stood to lose more through the credulity of the crowd than through its indifference or its scepticism.

The Council of the Zoological Society of Lond has instituted an Aquarium Research Fellowsh of the annual value of 350*l.*, tenable for one ye but with the expectation of reappointment for t further years if satisfactory progress is being mad The Research Fellow will be expected to give h whole time to his investigations, which will be carri out chiefly at the Aquarium in the Zoological Garde The object of the research is study of the conditio which affect the life of the organisms living in a aquarium, and not the anatomy, physiology, or lif histories of individual organisms. Candidates shou be recent graduates in honours in some branch science, and should be recommended as likely carry on research on independent lines. Experien of marine or fresh-water zoology is not require Inquiries should be addressed to the Secretar Zoological Society of London, Regent's Park, Londo N.W.8. It is not expected that an appointme will be made before October 15.

Dr. Fraser Harris, acting on medical advice, h resigned the professorship of physiology in Dalhous University, Halifax, Nova Scotia, which he has he since 1911.

During last week, an unusual contest was progress at the Crystal Palace, where Mr. C. V Hart pitted himself against a horse, Saucy Lassi in an endurance test. The test, which was to s which could cover the greater distance in six da came to an end on Saturday, August 23, when t total distances covered were: The man, 345 mil 880 yards; the horse, 337 miles 1618 yards. M Hart was thus the winner by 7 miles 1022 yards.

A physicist is required under the directorate radiological research of the Research Departmen Woolwich. Candidates must possess an honou degree in physics and at least three years' experien in research. Applications in writing, with tes monials and references to published work, should made to the Chief Superintendent, Research Depar ment, Woolwich, S.E.18.

Dr. W. J. Humphreys, of the U.S. Weath Bureau, Washington, would be glad if any observe of "ball lightning" would send him a comple description of the phenomenon with the followi details: date, witnesses, geographical position, tim during the storm, size, shape, sharp or blurry outlin whether with or independent of wind, direction motion (vertical, inclined or horizontal), kind motion (smooth or jumpy), effects produced, indoo or outdoors, and if the former how it entered.

A preliminary programme has now been issue of the centenary celebration of the Franklin Institu and the inauguration celebration of the Bart Research Foundation, to be held in Philadelphia September 17-19. The Franklin Institute has help in no small measure in the prosecution of researc into physical science and its applications during th past hundred years, and a noteworthy gathering physicists and engineers from both sides of th Atlantic is being brought together to celebrate th

niversary. Among the British men of science who e to deliver addresses are Sir Ernest Rutherford, r William Bragg, Prof. W. L. Bragg, Prof. E. G. ker, Prof. F. G. Donnan, Sir Charles Parsons, and of. J. S. E. Townsend. Other distinguished men science, exclusive of the large body of Americans, ho will be present, include Prof. Charles Fabry, of. F. Haber, Prof. W. Lash Miller, and Prof. P. eman.

THE southern slope of the Grasberg, in the valley the Dürren Ager, parish of Oberaschau, Austria, s been in motion. Portions of the forest have igrated to the valley, and landowners can no longer ientify their own areas. One man has a piece of rest tipped on him, but the timber is not his; nother has lost the meadows he intended to mow; ey have slidden away. The area of the landslide about 100 acres and is a quarter mile broad. The pth of the mass moved is not more than 50 feet, t it is not limited to the weathered surface. The hole slope has been soaked. Coloured or black ays and shales, dark grey "ruschel"-shales, interstratified between sandstones of the upper chalk, seem specially suitable for landslides. Two rows of stakes have been driven in so that measurements can be made to follow the movement.

WE learn that arrangements have been made by which Automatic and Electric Furnaces, Ltd., 17 Victoria Street, London, S.W.1, and Electric Furnace Company, Ltd., Elecfurn Works, 173-175 Farringdon Road, London, E.C.1, will jointly design Wild-Barfield internally heated electric furnaces having an input greater than 25 kw., which in future will be supplied by the latter firm. Automatic and Electric Furnaces, Ltd., will continue the manufacture and sale of the Wild-Barfield automatic hardening furnaces with magnetic detector, and internally heated type of furnaces up to 25 kw. Arrangements have also been made with George J. Hagan Co., of Pittsburg, U.S.A., who have constructed a large number of electric resistance furnaces up to 350 kw. capacity, for the use of their drawings and information, so that the best British and American practice will be incorporated in the designs.

Our Astronomical Column.

SOLAR SPECTROGRAPH FOR THE POULKOVO OBSERVATORY.—*Engineering* for July 18 contains a detailed escription and several photographs of the 7-metre lar spectrograph by Grubb, which has just been ected at the Poulkovo Observatory. The instruent, in which a grating is employed, is of the Littrow pe, and is modelled on the 30 ft. tower spectrograph Mount Wilson. The sun's rays are received on a elostat, for which a special erection is made at the p of the south wall of the Observatory, and are flected into an object-glass, after passing through hich they are reflected to the slit of the spectrograph the ground floor, where they form an image of the n about 10 cm. in diameter. The main object of e instrument is the study of the sun's rotation by eans of the Doppler effect shown by light from the stern and western limbs. By using a system of ur prisms, light from the centre and limbs of the n is made to fall simultaneously on different parts the slit, and the spectra are obtained in juxtaposition on a plate 24 cm. long by 4 cm. wide. The ectrograph lens has an aperture of 10 cm. and a cal length of 706 cm. No description of the grating given, but it is stated that the instrument will ve from one spectrogram a velocity measurement greater accuracy than 1/10th of a kilometre per cond in the line of sight. Arrangements are proded for rotating the instrument, the solar image maining fixed. The cœlostat, which has an erture of 25 cm., has been made adjustable for any titude between 60° and 37°, in order that it may be ed at the Simeis Observatory, in the Crimea, if sired.

THE LIVERPOOL ASTRONOMICAL SOCIETY, ANNUAL EPORT, 1923–24.—This body has undergone remarkble vicissitudes. It was founded in 1881 by Espin, aac Roberts, and R. C. Johnson, and proved so eful in helping beginners, and amateurs generally, at in a few years its membership rose to nearly 1000. hen a period of stagnation set in, and the publication its journal became very irregular. It was the alisation of its earlier usefulness that led to the formation of the British Astronomical Association in 1890. The competition thus afforded led to a distinct revival of the Liverpool body, though it has since been a local rather than a national body. War difficulties once more led to a suspension, but all will be glad to hear that meetings have now been resumed and that the outlook is hopeful. Papers were read during the session by the president (Dr. Whichello); by Mr. W. Porthouse on the moon; Mr. J. Rice on relativity; Rev. A. L. Cortie, S.J., on sun-spots and magnetism; and others.

While not at all endorsing the president's statement that the B.A.A. is too much under the influence of the professional astronomer to be of use to the ordinary amateur worker, we may freely admit that it is a great benefit to astronomers at a distance from London to have their own meetings both for discussion and observation; and doubtless all will join in wishing this society, the name of which recalls happy memories to many of us, a new lease of useful life.

ANNUAIRE DE L'OBSERVATOIRE ROYAL DE BELGIQUE, 1925.—This useful annual contains the usual almanac information about sun, moon, planets, stars, tides, etc. It gives very full information about wireless time-signals, and time determination. Incidentally it notes that while most of the national ephemerides adopt the new system of commencing the astronomical day at midnight at the beginning of 1925, the Berliner Jahrbuch adheres to the old system. It will therefore be necessary to state the system employed fully and clearly in all astronomical time determinations: it will be unwise to use the phrase Greenwich Mean Time for the new system without some distinguishing mark: Greenwich Civil Time is probably the best to use, but a warning is necessary that it does not mean Summer Time.

An error may be noted in the table of Periodic Comets on p. 168. The period given for Tuttle's Comet, 12·15 years, is far too short. The next return should be given as May 1926, not February 1937. Also the Comet Grigg-Skjellerup should be included as due to return in 1927.

Research Items.

SHORT CIST BURIAL IN KINCARDINESHIRE.—A short stone cist unearthed at Catterline, Kincardineshire, in March 1923, contained a fairly perfect male human skeleton which has been carefully examined by Prof. R. W. Reid and recorded by him and Rev. J. R. Fraser (Proc. Soc. Antiq. Scot., ser. 5, vol. x., 1923-24, pp. 27-40). The discovery revealed several unusual features. The covering of the cist, instead of being formed of a single series of large stones as is usual, was made up of several layers definitely arranged and graded, and embedded in sand three feet deep from top of bottom. One of the larger of the cover stones bore rude incisions in spiral and concentric circle form, but the weathering of the stone showed these were clearly handiwork of a much older date, and were not used as the artist had intended. Another of the cover stones was artificially perforated. The skeleton showed the ordinary characteristics of the round-headed bronze age race of north-eastern Scotland, with strongly platymeric limbs, but the skull capacity was unusually large, 1600 c.c., as against an average of 1458 c.c. for a considerable series of short cist skulls from the same region. The height of the individual was also out of the ordinary for his race, his stature, calculated from the leg bones, being 5 feet 10 inches, and calculated from the arm bones, 5 feet 8 or 9 inches. It would appear, however, that his arms were shorter in proportion to his legs than is the case in modern races. The average height of the short cist men of Aberdeenshire is only 5 feet 4 inches. The skeleton was accompanied by a low-rimmed clay beaker of the "drinking-cup" type, and by a fragmentary and rudely chipped quartzite pebble.

BIOCHEMISTRY IN INDIAN AGRICULTURE.—The Journal of the Indian Institute of Science, vol. vii. parts ii. and iii., contains two papers dealing with problems of considerable interest in connexion with Indian agriculture. In the first, G. J. Fowler and Y. N. Kotwal show, by a series of laboratory experiments, that dilute aqueous solutions of ammonium nitrite are not decomposed by other substances such as acids, amino-compounds, or hydrogen sulphide, which are likely to occur with them in ordinary agricultural or sewage disposal practice. Such loss of nitrogen as occurs in these operations cannot, therefore, be due, to any noticeable extent, to purely chemical reactions, but must be mainly the result of biochemical changes, as has indeed been generally assumed. The second paper deals with the retting of coconut husk for the production of coir. Coir is the fibre used in the production of coconut matting, and is therefore the basis of a large industry. So far as scientific investigation is concerned, it has been even more neglected than most of the coarse textile fibres, and Messrs. G. J. Fowler and F. Marsden are breaking new ground in tackling the problem. The fibre is obtained by soaking in water, which is changed from time to time for about ten months, the crude mass of fibrous tissue (mesocarp) which forms the husk of the fruit of the coconut palm. The natives who carry on this part of the industry have a good deal of rather indefinite and sometimes contradictory information as to the influence of various factors, such as the degree of ripeness of the fruit, the use of much or little water, the character of the water, and especially its salinity, on the quality of the fibre produced. Messrs. Fowler and Marsden find that the essential feature of the soaking process is the breaking down by bacterial agency of the material, described as insoluble gum or possibly a hemicellulose, which binds the fibre together in the husk. The necessary bacteri occur in the husk itself, and they remain active s long as the water is changed frequently enough t prevent them being poisoned by the products of th reactions they cause. The discoloration of the coi which sometimes occurs is due to changes in th tannin originally present in the husk, and the tannin under unsatisfactory conditions of soaking, ma oxidise to red insoluble products, which are deposite on the fibre, or if ferruginous water gains admittanc to the soaking areas, may form iron tannate, pro ducing "blue" fibre.

A NEW CERCARIA FROM NORTHERN INDIA.—Dr. B Soparkar describes (*Indian Journ. Med. Res.*, vol. xi. 1924) a new cercaria from northern India whic presents several unusual features. The tail is forke distally, and bears proximally two arm-like latera processes each terminating in an oval structure whic appears to be glandular and to serve as an organ c adhesion. The reproductive organs are much mor developed than is usual—the ovary and two lobulate testes being clearly marked, and numerous motil spermatozoa could be seen in the vesicula seminalis The entire length of the main excretory canal i ciliated. This cercaria develops in rediæ in *Melanoide tuberculatus*, but its further history after issuing fro the snail is unknown. The cercaria has not bee observed to encyst and it does not possess cysto genous glands; as it is not adapted for active penetra tion, the author suggests it is swallowed by the nex host.

INTERACTIONS OF PROTOPLASMIC MASSES IN *ARCELL POLYPORA*.—Bruce D. Reynolds (*Biol. Bull.*, vol. 4 Feb. 1924) finds that, like Difflugia, Arcella will, i favourable circumstances, reappropriate by fusio fragments of protoplasm which have been detache from it. Arcella is not attracted by a pseudopodia fragment of Difflugia, and if accidental contact i made the fragment is treated as a mechanical obstruc tion. Fusion will take place between one individua of Arcella and a protoplasmic fragment of a closel related specimen. Two distantly related individua which have not been kept in the same receptacle wi be attracted by each other's severed pseudopodia but upon making contact the protoplasm involve will be shattered into bead-like masses. When tw lines of a clone (a pure line) are kept under simila environments, cross-fusions between them cease aft about 22 days, but if the two diverging lines are kep under different environments, cross-fusions ceas after a shorter time—6 to 16·5 days. When sma quantities of culture media are frequently inte changed between the hollowed slides in which th members of two diverging lines are kept, cros fusions apparently continue indefinitely. When tw related specimens have become negative to eac other's protoplasm, cross-fusions between their pr geny may be induced by exchanging small quantitie of culture media or by placing them in the sam culture medium (time required, 6 days). Physic logical changes occur among the descendants of single Arcella reproducing vegetatively, but suc differences are probably due to environmenta influences rather than to hereditary variations.

EXPLOSIONS AND ZONES OF SILENCE.—Accordin to M. L. Gazaud's observations of the explosions a La Courtine on May 15, 23, and 25 made near Ma seilles, the zone of direct audition is very limited i extent (*Comptes rendus*, Paris Acad. of Sci., July 28

The explosions were in each case inaudible at the stations calculated from the distance, and the same was true at Montpellier. The explosion of May 15, however, was distinctly registered at both stations, but with retardations corresponding to extra paths of 70 and 135 km. respectively, the distance in a straight line from La Courtine being 360 km. At the same time a thick mass of cumulus cloud was observed, rising above the mountain masses of Ventoux and the Basses Alpes, forming an obstacle which was evidently quite capable of reflecting sound waves coming from La Courtine. Such a wall of cloud, if it were concave in front, could concentrate the sound waves so as to make them audible at certain points. A simple calculation of the probable trajectories for the two stations confirmed the above hypothesis, and fixed the probable points at the edge of the cloud mass where the sound was reflected. Reflection from above is shown to have been impossible in these cases, and that the height required to give such large differences of path, the pressure of the air would be very small, and very little sound would be transmitted.

NATURAL GAS INDUSTRY.—Three advance chapters of the Mineral Resources of the United States, volume for 1922, dealing with Natural Gas, Natural Gas Gasoline and Carbon Black produced from Natural Gas, contain significant data proving the rapid development of this industry in America. Consumption of natural gas in 1922 amounted in the United States to 762,546,000,000 cubic feet, being 15 per cent. more than the quantity used in the previous year. West Virginia, Oklahoma, and Pennsylvania ranked chief among the twenty-three producing States, each giving over 100,000,000,000 cubic feet, showing that the palæozoic compared with the tertiary fields are still the most important from the point of view of gas production. The unit value of the gas has also gradually increased, the average at points of consumption being 29·1 cents per 1000 cubic feet compared with 21·6 cents in 1919; the value in domestic consumption shows proportionate increase, being 49·9 cents per 1000 cubic feet in 1922. Unblended gasoline extracted from natural gas in the year under review amounted to 505,832,000 gallons, representing a 12 per cent. increase over the previous year and 8 per cent. of the total gasoline produced in America from all sources. The average yield of gasoline per 1000 cubic feet of gas thus works out at 0·9 gallon. Of the 917 plants in operation for the extraction of this product throughout the United States, those of the compression type produced by far the largest amount of gasoline, though statistics show that the combination process is steadily increasing in favour. The average value per gallon of natural gas gasoline was 14·4 cents in 1922. Carbon black manufacture likewise showed an increase of 1 per cent. over the previous year, amounting in 1922 to 67,795,000 pounds; the advance was largely due to the greater demand for this commodity in the rubber tyre industry. Louisiana and West Virginia together were responsible for more than 90 per cent. of the entire output of the country, the Monroe field of the former State contributing in no small measure to this result. The average price per pound of carbon black was maintained at 8·6 cents, a slight increase compared with 1921.

ACOUSTICS OF HALLS.—Owing to the pioneer investigations of the late Prof. Sabine, the factors which determine the acoustical properties of rooms are becoming known, and the provisional theory is being tested by the observations made in halls of various sizes and shapes by auditors whose opinions are of value. As the result of a considerable amount of work of this kind, Prof. F. R. Watson, of the University of Illinois, suggests in the July issue of the Journal of the Franklin Institute an improvement in the law expressing the best time of reverberation in a hall in terms of its volume. His expression for a hall without audience is, time in seconds $= 0{\cdot}75 + 0{\cdot}375\sqrt[3]{\text{volume}}$, the volume being in cubic feet. He concludes also that in increasing the absorbing material as the hall gets larger, it is best to keep the average absorption per unit area constant. This involves the energy of the sound source being proportional to the area of the surface of the hall.

THE QUANTUM THEORY OF RADIOACTIVE DISINTEGRATION.—In an article in the *Zeitschrift für Physik* of August 4, Dr. A. Smekal shows that the quantum mechanism proposed by him in 1922 gives a complete explanation, on the lines of the Bohr theory, of all the β-ray spectra which have so far been determined with certainty. Rosseland's criticism of this mechanism is ungrounded, and it is shown that he has simply applied the views of the author to explain the continuous β-ray spectrum of a very special class of β-ray disintegrations. The close analogy between X-ray and β-ray spectra supplies an explanation of the relationships found by Ellis and Skinner between the sequence of the nuclear levels in radium B and radium C. Wentzel has shown that "spark" lines are found in the X-ray spectrum, due to multiple ionisation, the terms of which bear a definite relationship to those of the normal lines. In a β-radioactive atom, instead of a recombination of an electron, as for X-rays, an electron is given off from the nucleus, or moved to an outer orbit. If two β-radiators follow one another in the periodic system, there is a close analogy with the case of a non-radioactive atom which has lost both its K electrons, and in regaining them will give spark lines, as well as the normal X-ray spectrum.

X-RAY ABSORPTION SPECTRA.—New measurements have been made of the fine structure of the K absorption band head of Ti, V, Cr, and Mn, and of the L_{III} band head of Sn, Sb, Te, and I, by Dr. D. Coster, *Zeitschrift für Physik*, July 2, and it is shown that the character of the structure depends on the chemical state of the element concerned. When the valency of the element in the compound used is high, an absorption line, Ka, $L_{III}a$, is found on the long wave-length (soft) side of the band head, but not for compounds in which the element has a low valency. It is thought that the principal band head corresponds to the sudden rise, from zero to a maximum value, of the probability for the removal of an electron from the layer concerned to infinity, when the wave-length diminishes to a particular value; the lines Ka and $L_{III}a$ are probably due to the removal of the electron to an inner electronic layer. The principal band head approaches the position of the Ka or $L_{III}a$ line as the chemical state of the element approaches that of the uncombined gaseous element. It may very well be that the lines Ka and $L_{III}a$ really exist in all cases, but can only be observed when the separation from the principal band head is sufficient. The author deals with the theory of this shifting of the band head and with that of the maxima and minima of absorption observed on the "hard" side of the band head. It is suggested that, in this region of the spectrum, besides the "photo" effect, there is another possibility, so that the atom may take up a larger energy quantum than that corresponding to the removal of an inner electron to infinity; the extra energy might be used in removing an electron simultaneously from

the outer layer; or the atom or atomic complex may be in some special state of tension after the absorption.

FIRST LAW OF PHOTOCHEMISTRY.—The Journal of the Chemical Society for July contains an important paper by Mrs. M. C. C. Chapman on the first law of photochemistry. This law, which was enunciated by Draper in 1843, states that the amount of chemical change in a given system effected by light of a specified wave-length is proportional to the light absorbed. Although this is a fundamental principle of great importance, its validity has not been conclusively established. Its accuracy has, in fact, recently been challenged by Baly and Barker, who found that in the case of the combination of hydrogen and chlorine, when the light intensity was increased in the ratio of 1 : 6, the rate of combination increased in the ratio of 1 : 10. Mrs. Chapman has carried out careful experiments with the same reaction, and the results show that the rate of combination appears, if anything, to increase with the light intensity rather less rapidly than is required by Draper's law. For the ratio of intensities 1 : 6, the ratio of rates of combination was 5·49 in one group of experiments and 5·67 in another. With six slits, the ratio of rates of combination occasioned by opening six slits compared with that with two slits was 1 : 2·97, 1 : 2·95, and 1 : 2·97. The deviation from Draper's law is ascribed to the temporary reduction in pressure of the water vapour occasioned by the formation of hydrogen chloride rather than to an inhibitive action of hydrogen chloride. The experiments were made in the presence of water. The conclusion reached is that the abnormal result obtained by Baly and Barker could not be substantiated, and that Draper's law is valid even in the case of the photochemical change which exhibits the greatest departure from Einstein's law of photochemical equivalence.

BAKERY RESEARCH.—A report on research work carried out at the National Bakery School, London, has recently been issued by Dr. C. Dorée and Mr. John Kirkland. It is divided into four sections, namely, (1) variation in weight of loaves due to loss in baking, (2) weight conserving effects of wrapping loaves in waxed paper, (3) variableness of oven temperatures, (4) quicker ripening of hard flour doughs. With respect to the first part of the report, the opening paragraph quotes the Report of the Inter-departmental Committee on the Sale of Bread by Weight which stated that, in spite of the difficulties encountered, it is possible to estimate with reasonable accuracy the loss which takes place in baking and after. The sale of bread by weight places the baker in a very difficult position, as it has been suggested that it is by no means easy to tell how much dough should be scaled off so that the resultant cooled loaf should just be the desired weight. No conclusions are directly drawn contradictory to the committee's considered opinion, but the mass of carefully collected data in this report throws very grave doubts on its correctness. Loss of weight is found to be affected by the tightness of the dough, by the position in the oven, by the kind and shape of the loaf in question, by the degree of ripeness of the dough, by the length of time the bread is in the oven, and by the presence or absence of certain moisture pastes chiefly of a starchy character. It is further shown that attention to these points is a matter of considerable financial importance to the practical baker. The second part of the report dealing with the effect of wrapping on the weight of the loaf is very limited in scope, although the results are of interest. It is shown that the expense of wrapping is partly met by the decreased loss in weight of the loaf on keeping. There was u fortunately no work done on the important questio of the increased cleanliness of the loaf. As to th variableness of oven temperature, it appears that the is often a range of temperature in different parts the oven of 50° F., and in some cases of more tha 100° F. It may be that some of the rather incor sistent results reported in the first part of this repo are due to this varying factor. The final part dea with the quicker ripening of certain hard and stron doughs. In view of modern labour conditions it necessary that something should be done to th stronger and slower ripening flours if they are to b ready for the oven quickly, and the practical sugge tion of the addition of lactic acid and the preparatio of pastes rich in lactic acids is made.

COAST DEFENCE WORKS.—The destructive effect the grinding action of shingle or boulders on concre structures erected on the foreshore is well known. D John S. Owens describes a method which has been use successfully on the south coast of England, and illu trates it with photographs in the *Engineer* for Augu 8. The method consists in facing the concrete s wall with wood blocks set in cement, with the en grain exposed. One of the photographs shows a experimental patch of wood blocks inserted in 192 and the wear of the unprotected surrounding concre has been from 1½ in. to 2 in. more than the woo The wood blocks indeed show but little signs of wea and it has been noticed that where a knot came the surface of the wood there was a definite hollo worn, the hard knot being worn more rapidly tha the surrounding soft wood. The experiments we regarded as so promising that a considerable leng of sea wall was faced this spring with wood block The blocks are mostly 6 in. square on the surfa and are set with headers 9 in. long at intervals, th other blocks being 6 in. deep. All the blocks we set in neat cement grout and were held in position the first instance by double-pointed nails, as one the difficulties encountered was to keep them correct position while the concrete behind was fille in and rammed.

LATERALLY LOADED STRUTS.—Technologic Pap No. 258 of the U.S. Bureau of Standards contains a account of some tests on steel tubing made by M Tom W. Greene with the view of ascertaining wheth experimental results confirmed the theory of lateral loaded struts. The range covered the cases of column without transverse load to that of a bea with no column load. It was found that the ecce tricity due to variation in wall thickness and deviation from straightness is an important facto A modified rational formula based upon considerati of the effect of eccentricity was found to fit th experimental results very closely. Failure of a str will occur when the maximum compressive stre computed by the modified formula is approximate equal to the yield point, and the modified ration formula reduces to the "secant" column formu when the transverse load is equated to zero. reasonably accurate computation of the stress in laterally loaded strut can be made by summing th bending stress due to the transverse load and th column stress obtained by the "secant" formula, pr vided that in the latter formula the effective ecce tricity is taken as the sum of the original eccentricit (due to tube irregularities) and the deflexion of th strut at the centre resulting from the transverse loa The methods of measuring the eccentricities in th test struts are clearly described in the paper, an judging from the exactness of agreement shown b the checks applied, appear to be very accurate.

The International Commission on Illumination.

THE second technical session of the International Commission on Illumination was held in Geneva on July 21-25, under the presidency of Dr. E. P. Hyde (U.S.A.). About forty delegates from France, Great Britain, Italy, Switzerland, and the United States of America were present, while observers from Japan and Poland attended the meetings. The delegates were welcomed to Geneva by M. Stoessel, president of the city, while Dr. Carrozzi, representing the health section of the International Labour Office, welcomed the collaboration of the Commission in problems which were of particular interest to his section. The president announced that national committees were in the process of formation in Belgium and also in the Union of South Africa.

At the first technical meeting two papers dealing with primary standards of light were presented by E. Crittenden (U.S.A.), on behalf of Dr. Ives, and by M. Fleury (France). Dr. Ives, by using a cylindrical platinum black body at the instant of melting, has obtained results which are considered sufficiently reproducible to make this type of black body a suitable primary standard. His results indicate that at the melting-point of platinum the black body has a brightness of 55·4 candles per square centimetre, and its radiation very closely colour-matches that of the carbon filament lamps operated at 4 watts per mean horizontal candle, in which the international candle is maintained. M. Fleury is using a carbon tube furnace held at such a temperature that the intensity of the radiation between two given wavelengths is N times that between the same wavelengths emitted by a black body held at the melting-point of gold. The power consumed in the furnace, and hence its temperature, is maintained constant by the use of a thermionic valve controlling a generator, and it is anticipated that the constancy of temperature will be sufficiently exact to enable the furnace to be used as a primary standard of light. As a result of discussion the Commission passed a resolution recommending that the brightness of the black body operated under definite specified conditions be adopted as the primary standard of light, and that the various National Laboratories be asked to specify conditions and to determine its value in terms of the international candle at present in use. An exceedingly comprehensive paper dealing with the properties of tungsten and the characteristics of tungsten lamps was presented by Dr. Crittenden (U.S.A.) on behalf of Dr. Forsythe and Dr. Worthing. Other papers were concerned with the description of an acetylene standard lamp for use in sensitometry, and of special holders for electric lamps used as photometric substandards.

The second technical meeting was taken up with the study of problems in connexion with photometric definitions and symbols arising out of the report of the international committee on definitions and symbols, presented by M. Fabry (France) on behalf of M. Blondel, and the reports of the various national committees. A technical sub-committee was appointed to deal with the recommendations, and agreement was reached on about fourteen definitions, in addition to those on which agreement was reached at the Paris meeting in 1921. Definitions were finally adopted of transmission, absorption and reflection factors, brightness, visibility, total flux, mean spherical intensity, reduction factor, efficiency of a source, and several other quantities. Symbols for luminous flux, luminous intensity, illumination, and for transmission, absorption, and reflection were also agreed upon.

The Italian National Committee presented a vocabulary of illumination in Italian, and it was agreed that it would be advantageous if there were corresponding vocabularies in English, French, and German. As the Swiss National Committee had already placed on its programme the collation of the Italian and French vocabularies, it was decided that this work should be extended by including English and German, and it was decided that a sub-committee with a Swiss chairman should be appointed to deal with the matter.

The third technical meeting opened with a paper by Prof. Fabry (France), chairman of the sub-committee on heterochromatic photometry, appointed at the Paris meeting. Prof. Fabry gave an excellent account of the work done since the Paris meeting on the subject of heterochromatic photometry, and of a programme of work which, if carried out by the sub-committee, would be of the greatest value. A paper was presented by Mr. H. Buckley (Great Britain) on behalf of Messrs. Buckley, Collier, and Brookes on the colour temperature scale for tungsten. Very satisfactory agreement with existing data was obtained in this preliminary work, which it is intended to repeat to greater accuracy. M. Jouaust (France) read an interesting paper on the use of absorbing screens in heterochromatic photometry. Dr. Crittenden (U.S.A.) presented a report on behalf of Mr. K. S. Gibson on the relative visibility function. This report reviewed the more recent work on this problem, including that by Messrs. Gibson and Tyndall, in which the step by step method of direct comparison of different portions of the spectrum was used. It appears from this work that, contrary to what had been suspected, the direct comparison method gives the same results as those obtained by methods involving flicker photometry. The Commission passed a resolution that the values recommended by Mr. Gibson should be adopted as provisional standard values of the visibility factor, except in certain specified cases such as arise in considering the ends of the spectrum or in particular conditions of field intensity and size. These new values differ only slightly from those recommended at the Paris meeting in 1921. The Commission decided at this meeting that the sub-committee on heterochromatic photometry should extend its activities to include the investigation of the transmission characteristics and the specification of coloured glasses, particularly of those glasses used in photometric measurements. It was also decided that a new committee consisting of three members should be set up to deal with colorimetry.

The fourth technical meeting dealt with street lighting and with certain aspects of illumination engineering practice. Mr. H. T. Harrison (Great Britain) presented a paper in which he developed the idea that street lighting should be more of the projection type, such as is associated with automobile headlights. Papers were also presented on street lighting in Paris by gas and electricity, and on some interesting traffic regulating signs recently installed in Paris. A proposal was made that the Commission should recommend the fixing of a legal minimum of illumination for street lighting. It was decided, however, that though it might be desirable for the Commission to give the weight of its opinion on street lighting, this was such a debatable subject that action had better be deferred pending further consideration, and it was agreed that at the next meeting the question of street lighting should be given greater prominence.

The papers on illumination engineering practice were the first of their kind which had been given before the Commission. In these, the authors, Messrs. Lieb, Merrill, and Powell (U.S.A.), gave an account of some of the features of the organised campaign which is being carried on in America to promote the widespread practical application of the principles of good lighting. Dr. Lieb urged that the work of the Commission should not be restricted merely to the theoretical aspects of illumination, but should be extended to include the practical aspects of illumination engineering so that it would be of benefit both to manufacturers and the general public. Mr. Merrill described the method of conducting good lighting demonstrations, while Mr. Powell described various types of propaganda work, and surveyed a large field of investigatory work in practical illumination engineering.

The fifth technical meeting dealt with factory and school lighting and with automobile headlights. Mr. L. B. Marks (U.S.A.) presented the report of the international sub-committee on lighting in factories and schools as a basis of international agreement. Recommendations of the minimum illumination in various circumstances, of the maximum brightness of light sources, of exit and emergency lighting, and of the colour and finish of school interiors, were made. There was general agreement that at present standard minimum values of illumination for working conditions should not have any legal force, and that whatever regulations are made should be based solely on considerations of the health and safety of employees. Mr. Gaster (Great Britain) presented a paper on some further developments in industrial lighting in England, and M. Bordoni (Italy) on some phenomena of glare. Dr. Sharp (U.S.A.), chairman of the international sub-committee on automobile headlights, presented a report in which the propos made by each of the various countries were reviewe while papers dealing with the photometry of au mobile headlights were presented by Messrs. Bos and Cellerier (France).

After the technical meetings were over a plena meeting of the Commission re-elected Dr. E. P. Hy to the office of president for the next three yea Mr. C. C. Paterson was also re-elected to the office honorary secretary and treasurer, and Mess Edgcumbe (Great Britain), Rouland (France), a Semenza (Italy) as vice-presidents, while Mr. Wal of the National Physical Laboratory, to whose abili and efforts the technical success of the meeting w so largely due, will continue his work as gene secretary for the next three years. It was provisio ally decided that the next meeting should take pla in the United States of America in 1927.

The meetings were held in the Palais Eynard, whi was kindly placed at the disposal of the Commissi by the City of Geneva. The delegates were ent tained at a motor excursion and a dinner at Belleri on the evening of Tuesday, July 22, by the preside and members of the Geneva City Council; and at dinner at the Hotel des Bergues by the Swiss Natior Committee on Wednesday, July 23. On July 24 t Swiss National Committee were the guests of t foreign delegates at a dinner held at the Parc des Ea Vives.

The Swiss National Committee, particularly t president, M. Filliol, and the secretary, M. Largiard were responsible for the excellent arrangements ma for the meeting, while M. Thomas, the director of t International Labour Office, very kindly placed secretarial staff and interpreters at the disposal the Commission. H. B.

The Automatic Measurement of Atmospheric Pollution.[1]

By Dr. J. S. Owens.

THE suspended impurity in the air can be measured by two methods, the automatic recorder or filter, and the jet dust counter method. The former was designed primarily for measurement of smoke pollution, and depends upon filtration of the air through white filter paper, the resulting discoloured spot being compared with a calibrated scale of shades. In the dust counter method the results are independent of the colour of the particles, a count of their number as well as an examination of their size, shape, and nature being made microscopically. Curves showing the numerical value of the suspended impurity for different cities and its variation from hour to hour can be plotted from the average figures for a large number of days. The cities selected for this purpose were London, Rochdale, Blackburn, Glasgow, and Stoke-on-Trent.

The London curves of impurity for Westminster, Savoy Hill, and Kew Observatory indicate that the impurity is lowest between midnight and 6 A.M., after which it rises rapidly to a maximum between 9 and 10 A.M., falling again steadily until about 4 in the afternoon, when there is a tendency to rise slightly to a second but lower maximum. At about 10 P.M. the impurity falls away until about midnight. The Sunday curves are similar, but the maximum in the forenoon is not reached until about an hour later. The rise of impurity between 6 and 7 A.M. is attributed to the lighting of fires, the smoke from which is emitted in greatest quantity soon after lighting.

In plotting the curves referred to, it was found advisable to divide the days into two groups :

[1] Substance of a paper read before Section A (Mathematics and Physics) at the Toronto meeting of the British Association.

(*a*) Days in which there was much smoke ha at some time, as indicated by the automatic recorc showing a shade number equal to or above 4 equivalent to 1·28 mg. per cubic metre. These we referred to as " Z " days.

(*b*) Days of little smoke haze when the maximu did not reach Shade 4.

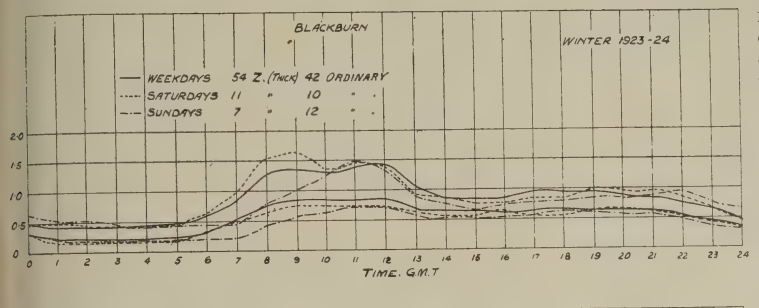
As the existence of thick smoke haze over a ci on certain days is due rather to failure of the natu processes by which normal smoke is removed produced, than to abnormal smoke production those days, this division is an attempt to separa ordinary days from those in which the ventilati fails, usually during anti-cyclones with light indefinite winds and inversion of the lapse rate.

The distribution of impurity for Rochdale a Glasgow is very similar to that in London. T records from Blackburn exhibit certain peculiariti These were prepared from an average of 269 da for the year 1923–24, 136 being winter—72 of whi ranked as " Z " days, that is, days of much smo haze.

The hourly distribution in Blackburn has certa important peculiarities; for example, a rapid r of impurity commences in the morning in the summ about 4 A.M., and reaches its maximum on wee days and Saturdays at 7 A.M., while on Sundays t maximum is not reached until 10 A.M. Again, the week-day and Saturday curves there is a seco maximum between 10 and 12 in the forenoon, high than the first, and separated from it by a 4-ho interval.

It is inferred from this that there are two ma sources of smoke, making their maxima at differe

nes. The Sunday curves show no evidence of a ouble maximum in the forenoon. It is therefore ferred that the first maximum is due to industrial d the second to domestic smoke. In support of is is the fact that in winter the second maximum higher than the first for week-days, while in summer e first is higher than the second. The relation



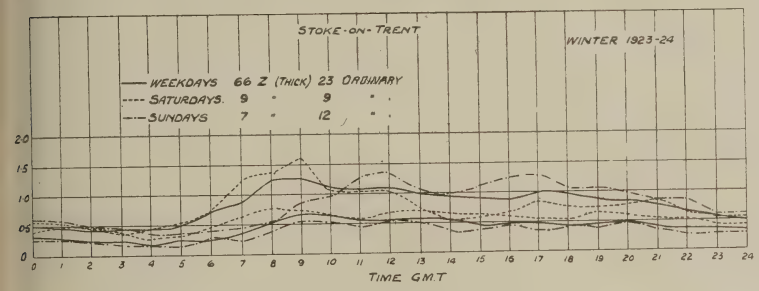


Fig. 1.—Suspended impurity in the air.

etween the total smoke emitted on Sundays and on week-days is as 2000 to 3077, based on the curves for rdinary winter days—not ranking as "Z" days. f the Sunday smoke be assumed to be domestic, nd the week-day smoke domestic plus factory, the atio of factory to domestic smoke becomes 1 : 1·85.

Stoke-on-Trent exhibits even more peculiarities han Blackburn. Stoke is a pottery ity containing about 2500 ovens. Records are available for a total of 22 days, including 126 winter days —82 of which ranked as "Z." Thus of the winter days recorded 65 per cent. had thick smoke haze, hat is, on two out of every three lays.

Fig. 1 shows that a definite rise egan about 4 A.M. on week-days nd 5 A.M. on Sundays. On summer week-days and Saturdays the maximum is reached between 7 and 8 A.M., while in the winter on week-days and Saturdays the maximum is between 8 and 9 A.M., and on Sundays about mid-day. In both summer and winter the impurity is maintained at a high level during the whole afternoon, but with remarkable oscillations, not shown in the records of the other cities mentioned. The minimum impurity is found at about 3 A.M.

The amount of suspended impurity in Stoke on ordinary winter Sundays is not much less than on week-days, the ratio being as 2022 to 2398. Here there are evidently conditions which make it impossible to apply the method already used for ascertaining the relation of factory to domestic smoke. In all the Stoke records for summer and winter, the Saturday maximum in the forenoon is the highest. This can be traced to the custom of lighting pottery ovens on Friday night or Saturday morning.

The incidence of atmospheric impurities on different days of the week has also been examined for six different cities, from which it appears that there is a general tendency to a minimum of smoke haze towards the end of the week, and a maximum about the beginning.

Since the records of the automatic instrument upon which the above conclusions were based depend upon the discoloration of a filter paper by the trapped impurity, experiments were made in which the results obtained with the dust counter method referred to were compared with those by the automatic recorder. In the latter, which was intended for recording city smoke, the impurity is assumed to be black, whereas the dust counter is independent of colour.

In the latter, fully described elsewhere,[2] the action depends upon the projection of a narrow ribbon-shaped jet of air against a microscope cover glass at such a velocity that a marked fall of pressure occurs with adiabatic expansion and cooling of the jet and consequent condensation of water, supplied from a damping chamber, upon the dust particles and the cover glass where the jet impinges. This results in the dust particles being projected against the cover glass by virtue of their greater density, and their increase of mass due to the condensed water. They adhere to the glass as the water evaporates, leaving a linear trace of dust, which can be examined microscopically and counted.

Simultaneous observations were taken with both instruments, and the results plotted in Fig. 2. From this curve it is evident that there is a reasonably constant relation between the number of

particles per cubic centimetre, and the weight of impurity in milligrammes per cubic metre as given by the automatic recorder.

This indicates a tendency towards uniformity in size of the particles at different times, but there is also a definite departure from such uniformity during thick smoke haze when the average size increases, doubtless due to insufficient time for separation by

[2] Proc. Roy. Soc. A, vol. 101, 1922.

settlement. The maximum diameter of smoke particles in the absence of thick smoke haze is about 1½ microns, while during thick smoke haze the maximum reaches about 3 microns. Fig. 2 shows that the relation in London between number and weight of particles is usually such that 10,000 particles per c.c. corresponds to 1 mg. per cubic metre. It is not suggested that this relation holds good for all types of dust, but it shows that the automatic recorder gives trustworthy comparative results for city air, where the colour of the suspended particles is usually black.

Horticultural Research.

THE growing recognition of the importance of research work in connexion with the fruit industry is emphasised by the Annual Report issued by the National Fruit and Cider Institute at Long Ashton, Bristol. The year 1923 was the first since the outbreak of the War in which the work could be conducted under relatively settled and stable conditions, and it was marked by steady progress as regards both advisory and research work. The direct and practical bearing of the research work upon the current problems of fruit growers is very noticeable, and though many of the results are still preliminary or tentative, they open up suggestive lines for future progress.

The manurial experiments on fruit trees in pot cultures have been continued to study the effect upon growth of the omission of the various essential elements in turn. Leaf scorch affected many of the plants, but an increase in the amount of potash entirely prevented the development of scorch, while a reduction of nitrogen retarded it and reduced its amount. An examination of the root systems of various fruit trees shows that under many systems of planting there must be considerable overlapping of roots, introducing a serious element of competition which probably acts as a severe check to growth in many cases. This research is being continued in connexion with the danger of planting up orchards of large trees with soft fruit, if the latter is left too long on the ground. In connexion with the damage wrought by the apple blossom weevil it is pointed out that isolated efforts of control are unlikely to be efficacious, but that co-operative action is essential for success. Direct control methods must be associated with hygienic conditions in the fruit plantation, and a scheme of procedure is outlined, embracing a sequence of scraping, spraying, and banding the trunks, followed by the collection of capped blossoms in May. Other pathological investigations deal with egg-killing washes, the effect of sulphur on black currant mite, "red plant" in strawberries and its correlation with "cauliflower disease," purple leaf blotch of strawberry, and the infrequent disease of pear leaf blister.

A most interesting investigation is that of cold process fruit preserves. Under ordinary methods of preparation, jams, jellies, and fruit juices are subject to prolonged high temperature, to the detriment of their flavour, colour, and aroma. With the "cold" method the consistency of the product must be such that micro-organisms do not develop, a condition that can be secured by increasing the sugar content to 62-65 per cent., or less if the acidity of the fruit is high. Jellies and fruit juices give very satisfactory results, but more difficulty is experienced with the jams. Large-scale trials are being made to determine whether these methods are suitable for development under commercial conditions.

Another aspect of the work is shown by experiments on the "buffing" of willows, a process whereby, after prolonged boiling in water, a mineral-brown colour is imparted to the wood of willow rods. Freshly cut willow rods can only be peeled for a short time in the spring, owing to the rapid production of new wood which interferes with satisfactory peeling. "Buffed" rods can be peeled throughout the year, and the introduction of the process has been of great importance to the growers and to the basket industry. Improved methods are being sought and possibilities of industrial application worked out.

The chief lines of work at the Fruit and Cider Institute have been touched on above, but various other researches are being carried out, some of which may lead to more extended inquiries in the future, and others are of importance in their relation to the main investigations.

Problems of Human Nutrition.

THE investigation of human nutrition dealt with in the report before us[1] was undertaken in the autumn of 1922 during a period of depression for those engaged in the coal mining industry. Details regarding the actual food consumption were obtained from 140 families distributed in five different counties. The general result of the inquiry shows that though the average consumption of food in Derbyshire was sufficient for a healthy life when judged by accepted standards, the average diets in Northumberland, Lancashire, Stirlingshire, and in particular Durham were not so satisfactory. In the latter county the weight of the miners' children was slightly below the county average, though it seems probable that factors other than a deficient diet may have been partly responsible for this. The Committee is cautious in drawing conclusions, since the number of families investigated was not large, and it was recognised that the method adopted of reducing each family to the equivalent of "average men" for the purpose of assessing the nutritional value of the family diet is not free from objection.

The Committee has assumed that the average daily food requirement of a miner is equivalent to some 3400 calories. This figure has, however, not been ascertained by direct observation, but is inferred from a consideration of the numerous data already available on the energy output of man under different conditions of rest and work. Prof. K. N. Moss, in an investigation of the effects of high underground temperatures on the miner, has recently given details of the actual food consumption of a selected number of miners in different districts who had a high reputation for steadiness and industry. These figures show an average daily energy intake of well over 4000 calories, a value much in excess of that assumed by the Committee. Moss's selected subjects were clearly well above the general average, but if we regard the Committee's estimate as approximately true for this general average, it is apparent that there may be very great differences of energy expenditure between different individuals employed in the same industry. It is not alone the actual work done in the mine that matters, for much energy may be expended by the miner in walking to and from his work and in recreation in his spare time: as regards the last two items there is the possibility of great individual and local variations.

It is evident that further investigation is required regarding the actual energy output under everyday conditions not only of miners, but also of workmen in

[1] Medical Research Council. Reports of the Committee upon Quantitative Problems in Human Nutrition: Report on the Nutrition of Miners and their Families. Pp. 59. (London: H.M. Stationery Office, 1924.) 1s. 3d. net.

er industries involving heavy manual labour. So lg as uncertainty prevails as to the true energy quirements of the individual, the assessment of the ritional value of the family diet in the manner opted by the Committee cannot acquire its full ue. In times of financial stress the full diet of wage-earner may have to be maintained at the ense of other members of his family, and the ldren may in the end be the real sufferers. It is be hoped that the Report of the Committee is but prelude to further investigations which will dispel obscurity which still surrounds some of the portant practical problems of human nutrition. e work is bound to be very arduous, but it is worth ng, for apart from its value to the physiologist it s a direct bearing on modern economic questions.

Haddock Biology.

MR. HAROLD THOMPSON has made a useful contribution to our knowledge of the life-tory of the haddock in the report before us.[1] is fish is of increasing commercial value, and its undance fluctuates considerably from year to year. the researches which Mr. Thompson describes, he rtainly brings nearer the time when the causes of ese fluctuations will be better understood, and he reshadows the possibility of being able to predict two or three years ahead any special scarcity or undance of the fish in a particular area such as the rth Sea.

Great importance has been attached to the accurate termination of the age of the fish. For the haddock has long been recognised that the most trustworthy terminations of age can be got by studying the rkings on the scales. The author has, however, bjected the whole method of age determination in is fish by means of the scales to a minute and tical examination, and especially has been at great ins to study scales taken from many different parts the body. This careful but tedious examination s justified the methods employed, and the satis-tory conclusion has been reached, that if a few rmally shaped scales be taken from a haddock, it possible in about 95 per cent. of cases to read the e from the number of annual zones marked on em; and further, that by measuring these zones d comparing their length with the total length of e scale in each instance, one can calculate the sizes tained by the fish at the end of each previous year its life.

The author considers that North Sea haddock grow the average 17·5 cm. in the first year, though the nge of size is considerable, from 11 to 21 cm. The eatest growth in this, as in other years, takes place the autumn, and growth practically ceases in ovember, when the scale has formed about 22 rings clerites). The first scales make their appearance hen the fry are about 3 cm. long. In 1922 and 921, yearling haddock were sparsely represented in e North Sea, but the 1920 brood was extremely undant, as shown by the prolific numbers of one-ar-old fish in 1921 and two-year-old fish in 1922, the later months of which year they formed the ainstay of the Aberdeen market haddock supply. he year 1904 was a similar good brood year for addock and was followed by an abundant fishery of ree-year-old fish in 1907.

The rate of growth of the haddock varies in different gions. In the same latitude the best grown fish are found in shallower and warmer water, whereas there is a diminution in growth rate with increase of the depth from which they are captured. South Iceland and Faroe haddock exhibit faster growth than those captured in the North Sea and off the northern coasts of Scotland, for there favourable temperature conditions occur throughout the year, and the temperatures are so much less variable that it is often difficult to note the annual zones on the scales.

The paper is a valuable contribution to the literature of British fisheries.

The Iron Ores of China.

THE widespread distribution of local iron smelting in China led to the general belief that China possesses some of the greatest reserves of iron ore in the world. More careful investigation has failed to confirm some of the earlier estimates, and has led to the under-rating of the quantity of available Chinese iron ores. The series of Memoirs on the iron ores and iron industries of China, of which the first part by F. R. Tegengren has been issued by the Geological Survey of China,[1] will correct the wild statements that have been made on both sides. The first part deals mainly with the ores of the northern and eastern provinces, and is accompanied by 16 plates and a folio atlas including 39 maps. The first map, in which the names are conveniently given both in English and Chinese, shows the general distribution of the iron ores in eastern China. It does not mark those in far western China, where there are many primitive furnaces which smelt iron for their neighbourhood. Their supplies of ore are ample, but are too remote to be of service except locally at the present time.

The Chinese iron ores are of three main types. The first type comprises the pre-Cambrian bedded ores, including the banded quartzitic ironstones that are widely spread in western Australia, India, and South Africa. Of the pre-Cambrian ores the most interesting geologically are the stromatolitic ironstones, of which one of the best known representatives are the Wabana ores of Newfoundland. The author discusses their origin and attributes them to chemical precipitation; he discourages the view of their organic origin, though on grounds which are not convincing; and he recognises that they may indicate the existence of pre-Cambrian life. The second group includes the contact ores which have been formed beside intrusive masses of granodiorite along the lower Yangtze; they include some of the most important and extensive iron ore deposits in China. The third group includes the nodular ironstones of the Palæozoic rocks and they are found especially in north central China. They have been largely mined for the local smelters, and exaggerated estimates have been often formed of their quantity. The author concludes that in most cases the nodules are in beds too thin and too scattered to be of value for working under present conditions on an extensive scale.

The text is issued in both English and Chinese. The volume and the maps are well printed and edited; misprints, such as are probably inevitable when a work by a Swedish author is issued in English and printed in China, are commendably few, though the reversal of the headings of phosphorus and silica in the table on p. 38 gives at first a startling aspect to the analyses. The subsequent parts of this important memoir will include a summary of the distribution of the iron ores of the circum-Pacific region. J. W. G.

[1] "The Iron Ores and Iron Industry of China, including a summary of the iron situation of the Circum-Pacific Region." By F. R. Tegengren, Mem. Geol. Surv. China, Ser. A, No. 2, Pt. I., 1921–23, 180 pp., 16 pls. Accompanied by Atlas of 39 maps. Also Chinese Text.

University and Educational Intelligence.

APPLICATIONS are invited for two professorships in the Latvian University at Riga, namely, astronomy and theoretical mechanics, and geology and palæontology, the duties of which will date from January 1 next. The appointments will be for five years only, as at the end of that period the lectures will be delivered in the Latvian language. Applications for the posts should be sent to reach the Dean of the Mathematical-Natural Science Faculty of the University not later than November 1.

THE University of London Commerce Degree Bureau and Appointments Board has issued a useful little pamphlet entitled "Information as to Appointments and Careers for Graduates and Students." It has nineteen chapters on as many different classes of occupation — Teaching, Commerce and Industry, Civil Service, The Church, Law, Medicine, etc.—and concludes with a bibliography and "list of useful addresses." Copies are obtainable (price 1*s.*, post free; to members of the University of London, 6*d.*) from the Secretary of the Board, 46 Russell Square, London, W.C.1.

EDUCATION in relation to foundry work forms the subject of a useful report drawn up for the Board of Education by one of H.M. Inspectors, with the advice and assistance of Profs. C. H. Desch and C. A. Edwards. The unsatisfactory conditions affecting recruitment and training in the foundry trades have for some time engaged the attention of the British Cast Iron Research Association, the Non-Ferrous Metals Research Association, and other bodies. Unless these are improved, the general standard of foundries in Great Britain, even now lower than in the United States and several countries in Europe, is bound to deteriorate.

THE Indian Universities Conference held in Simla last May is the subject of an article in the June issue of the *Indian Review* by Mr. P. J. Hartog, Vice-Chancellor of the University of Dacca, formerly Academic Registrar of the University of London. One of the most important of the 44 resolutions passed by the conference was one proposing the establishment of an Advisory Board for Scientific Research, to comprise the heads of the scientific departments of the Government of India and a representative of science nominated by each of the Indian universities and by the Indian Institute of Science, Bangalore, with powers to co-opt representatives of other recognised institutes of science not affiliated to any university. There already exists a committee for medical research in India which has accomplished valuable work, showing that co-operation of this kind is practicable in India. Mr. Hartog infers, from the sympathetic reference made to the project by the Member for Education, that it may be realised at an early date. Commenting on the unanimous decision of the conference to request the Government to exempt scientific apparatus and chemicals for universities and other approved educational institutions from the payment of the 15 per cent. customs duty, Mr. Hartog remarks: "It seems absurd that while the charge on power-driven machinery is only two and a half per cent., that on brain-driven machinery is six times as great. The educational industry in India is a key industry, I might say the master-key industry, which perhaps needs more encouragement than any other."

THE purpose of education in schools is discussed at some length by the president of the Carnegie Foundation for the Advancement of Teaching in his annual report for 1922–23. The educational revolutio which has produced a great machine for the mas in place of a personal direct agency for the few ha brought with it certain dangers. The school bega as an agency for the development of the individua for the discipline of the mind and character, b methods involving intimate touch between teache and pupil. The machinery of organisation necessar for giving effect to the modern doctrine of universa compulsory education tends to obscure this purpos and the fundamental truth, stressed by the Arch bishop of York in his address on April 21 to th National Union of Teachers, that in the developmen of a human soul it is not the amount of informatio absorbed that counts, but the ability to think clearl and to bring out the right answers to the problem that present themselves in after life. For this th school is dependent on living contact between th growing mind of the child and the cultivated mind o a teacher whose primary qualifications must be inte lectual sincerity and moral simplicity and thorough ness. Paul Klapper, Dean of the College of Educa tion of the College of the City of New York, has con tributed to the March-April number of the *America Review* an article on "Educational Aims and Socia Progress," in which he similarly urges that educatio should "make power rather than information it final hope." This conception of the function of th school implies a demand for the critical examina tion and, when necessary, simplification of existin curricula and limitation of the size of classes.

THE London County Council has issued a Handboo of the lectures and classes for teachers which hav been arranged for the season 1924–1925. Thes lectures play an important part in connexion with th education of the Londoner. The successful teache must always remain a student, and these lectures ar designed to bring him into touch with the late developments in educational methods and to giv him opportunities of hearing leading authorities o their own subjects. Any person engaged in teachin in London is eligible for admission at fees whic average less than 1*s.* a lecture, while out-count teachers and others are admitted at fees 50 per cen higher. The lectures scheme is self-supporting, an last year the attendance was more than 16,000 Among the courses and lectures of interest to scientifi workers are the following: Prof. C. K. Tinkler (6 on fuels and ventilation; Prof. A. Morley Davies (6 on the geology and geography of the London basin Prof. E. J. Garwood (10), on the scenery of Switzerlan and its origin; Prof. E. H. Neville (6), on the element of the theory of curvature and curvilinear co-ordinates Mr. P. Abbott (10), on the teaching of arithmetic Prof. T. P. Nunn (9), on the teaching of mathematics trigonometry, and map-projection, and (5), on th teaching of physical science; Dr. C. W. Kimmin (3), on modern movements in education; Mr. W. H Winch (3), on the conditions of valid experiment i pedagogical methods; Dr. F. H. Hayward (5), o individual versus mass methods in education; Prof Cyril Burt (5), on mental and scholastic tests; Dr Charles Singer (10), on the history of science; Prof C. A. Carus-Wilson (5), on the teaching of science i secondary schools; Capt. P. P. Eckersley (4), o wireless telephony and broadcasting; Mr. Richar Kearton (5), on wild life round London; Maj. T. F Chipp (5), on Kew Gardens. Special single lecture are to be given by Sir Ronald Ross on malaria an mosquitoes (October 4), and by Prof. Karl Pearso on the relationship of mind and body (November 15) Copies of the Handbook can be obtained from th County Hall, Westminster Bridge, London, S.E.1.

Early Science at the Royal Society.

ugust 30, 1663. Mr. Colwall gave in an account ich he had received in a letter from the governor of Helena, concerning the tides, winds, springs, spouts, d weather there.—Mr. Colwall also mentioned, that . Thorowgood, a master of a ship, who had received tructions from the society for the East-Indies s returned, and had some account to give of what had done for the society in his voyage; which was desired to bring in.—Mr. Hooke produced explications of the new sounding instrument, and the vessel, that fetched water from the bottom the sea; and of the engine for determining the ce of gunpowder by weight. He was directed to aw the figures in great against the next meeting.

1666. Sir Theodore de Vaux produced some papers, ich were read, containing a relation of a furred e, made of the skin of the Tartarian boramez, pposed to be a plant animal; which robe was d in that paper to be kept in the library at ford, to which it was given by Sir Richard Lea, bassador in Russia in the reign of Queen Elizabeth. . Wren was desired to inform himself concerning is robe, and to view it on his return to Oxford.—r Robert Moray mentioned, that the King had been coursing of ant's eggs, and inquiring how they me to that bigness, which sometimes exceeded at of the insect itself.

eptember 2, 1663. The experiments of closing up gunpowder, *Aurum fulminans*, and water, in ree balls of steel severally, being again made; and at with gunpowder alone being fired and broken, it s debated, what might be the cause, that the npowder should fire, and not the gold powder; e latter being the stronger of the two?—Some nceived, that a sulphureous matter might exude t of the heated steel, and be communicated to the ld powder, whereby its fulminating virtue might deadned.—Others thought, that this powder ight fire within the ball (having left some air in it, cause not filled full with the powder) and the ise not be heard at a distance. Others were of inion, that the penning it in, and giving it but a w heat, might make it melt. It was ordered reupon, that the operator should bespeak two lls with cavities no bigger than a pea, to fill them ll severally with *Aurum fulminans* and gunpowder.

September 3, 1662. The president gave an account the society of his and the council's address to the ing in the name of the society, to return their mble thanks to his majesty for his favour in tablishing them into a corporation by his letter tent; with his majesty's answer of his peculiar teem of the society, and his readiness to give em all due encouragement: as likewise of their ldress of thanks to the lord chancellor [Clarendon] r his readiness to further that business; by whom ey were very favourably received, and assured, at it was his purpose to come himself to the society express his acknowledgments to them.

September 4, 1661. A proposition of Mr. Hobbes r finding two mean proportionals between two rait lines given, was delivered into the society by ir Paul Neile from the king, indorsed with his ajesty's own hand, and was ordered to be registered; s was afterwards the answer to the problem, by rd viscount Brouncker.—Mr. Wren was desired kewise to deliver a copy of his observations and ypothesis of Saturn to the amanuensis, to be trans-itted by Sir Kenelme Digby to Monsieur Frenich.—t was ordered that a collection of all quicksilver xperiments be made, examined, and brought in by Ir. Oldenburg.

Societies and Academies.

PARIS.

Academy of Sciences, July 28.—M. Guillaume Bigourdan in the chair.—Charles **Moureu**, Charles **Dufraisse**, and Marius **Badoche**: Auto-oxidation and antioxygen action. The catalytic properties of sulphur and its compounds: generalisation of the phenomenon. A detailed study of the action of sulphur and its compounds in the catalysis of auto-oxidation. Six oxidisable compounds were selected and a large number of inorganic and organic compounds of sulphur taken as catalysts. A summary of the more important results with benzaldehyde, acrolein, styrolene, turpentine, linseed oil, and sodium sulphite is given.—J. **Bordet**: The current theories of anaphylaxy. A critical review of the various theories which have been put forward to explain anaphylactic shock.—Henri **Jumelle**: Neodypsis and Chrysalidocarpus, palm trees of Madagascar.—F. **Gau**: The equation of the deformation of surfaces.—**Siegle** and **Cretin**: The elastic limit and resistance of annealed mild steels in the case of combined traction and torsion.—Th. **Vautier**: The propagation of explosive waves. An account of experiments on the transmission of sound waves in a tube one metre in diameter and several kilometres in length.—J. **Cayrel**: The influence of the pressure on the working of wireless detectors with solid contact. The pressure should be such that the mean resistance of the detector is of the same order of magnitude as the impedance of the circuit associated with the detector. If the impedance of the circuit is high the pressure should be small.—F. **Wolfers**: Interference by diffusion.—P. **Lebeau** and M. **Picon**: The action of heat and a vacuum on artificial graphite. In an apparatus described in an earlier paper the authors have utilised an electrically heated graphite tube. A preliminary study of the tube was necessary to determine the nature and amounts of the gases given up to a vacuum on heating. The present communication gives the results obtained.—Robert **Stumper**: The kinetic study of the decomposition of calcium bicarbonate in aqueous solution by heat.—Mlle. Jeanne **Liquier**: The anomalous rotatory dispersion of acid solutions of nicotine in relation with the concentration in hydrogen ions.—C. **Matignon** and C. **Faurholt**: A new synthesis of oxalic acid. At a temperature of about 470° C. and under a pressure of about 240 atmospheres, carbon monoxide reacts with potassium carbonate and some potassium oxalate is formed. The highest yield was 27 per cent. of potassium oxalate.—A. **Cornillot**: The constitution of phthalonic acid. Researches on its combinations with aniline. In the reactions studied, phthalonic acid reacts principally as an oxylactone, but a small proportion is clearly shown to react in the ketonic form.—Mme. Pauline **Ramart**: Molecular transpositions. The preparation and dehydration of 1 : 1 : 3-triphenyl-2 : 2-dimethyl-1-propanol. This compound on heating to 325° C. in the presence of infusorial earth gives isobutylbenzene and benzophenone; dehydrated with acetic anhydride and acetyl chloride, two isomeric hydrocarbons, $C_{23}H_{22}$, are produced.—E. **Asselberghs**: The existence of a fault in the French Ardennes.—J. **Savornin**: Geology of the Haut Guir and of the Moyenne Moulouya (Morocco).—L. **Gazaud**: Zones of silence. The zone of direct hearing, concentric with a focus of sound emission, is of very limited range; the zone which succeeds it is alternately one of hearing or of silence according to the presence or absence of high compact clouds.—Ph. **Schereschewsky** and Ph. **Wehrlé**: Perturbation currents and the polar front.—H. Colin

and A. Grandsire: Green leaves and chlorotic leaves: the ternary materials.—I. A. Christiansen, G. Hevesy and Sn. Lomholt: Researches by a radio-chemical method on the circulation of lead in the organism. There is an essential difference between the results obtained with bismuth and with lead. The quantities of lead accumulated in the liver and eliminated by the fæces are greater, at the expense of the amounts found in the kidneys and urine. With bismuth the latter organs play the principal part in elimination. —A. Fernbach and I. Stoleru: The influence of the reaction of the medium on the antiseptic properties of the hop. The antiseptic power of hops depends essentially on the hydrogen ion concentration of the culture medium.—E. Kayser and H. Delaval: Contribution to the study of wine yeasts.—Henri Stassano and A. Rollet: The carbonic acid removed from milk by the usual method of pasteurisation. The advantage of treatment in a closed circuit.—A. Demolon and Mlle. V. Dupont: The resistance of soils to acidification.—R. Argaud and D. Clermont: The glandular behaviour of the chordome.—Robert Ph. Dollfus: Polyxenia and progenesis of the metacercaria larva of *Pleurogenes medians*.

CAPE TOWN.

Royal Society of South Africa, July 16.—Dr. A. Ogg, president, in the chair.—D. J. Malan and D. E. Malan: The spermatogenesis of *Locustana pardalina* (Walker). (The Brown Trek Locust.) The chromosome numbers in more than 40 genera of locusts have been worked out, and in practically all cases it has been found that $2n = 23$ (male) and 24 (female). The few exceptions could all be accounted for by secondary linkage of non-homologous chromosomes.—H. O. Monnig: A new trichostrongylus from South African sheep. A description is given of *Trichostrongylus rugatus* n. sp. which occurs in the first 8 to 12 feet of the small intestine in South African sheep.—K. H. Barnard: The digestive canal of Isopod Crustaceans. The stomach (fore-gut) in a large number of Isopods of various families has been compared with that of Ligia, which may be taken as a basic type. A general agreement exists between the stomachs of omnivorous or herbivorous forms and those of parasitic forms, but with certain modifications due to the physiological differences in the mode of obtaining nourishment.—John Hewitt: Facts and theories on the distribution of scorpions in South Africa. The prevalence of primitive types in South Africa seems definitely against the probability of a South African origin for the families concerned. Assuming that the region of greatest differentiation of a group is its centre of dispersal, then we must look to Eurasia as the immediate source of scorpion fauna. But in most of the genera we find clear evidence of local evolution. These centres are different for different genera. Lines of gradational series of forms are explained as phylogenetic series ranged along former routes of migration, the simplest and oldest forms having migrated farthest from the centre of origin.—A. W. Veater: (1) Note on covariants and invariants of binary quantics. (2) Note on differential invariants of the group of homographic transformation of a plane and of certain sub-groups.

SYDNEY.

Royal Society of New South Wales, July 2.—Dr. C. Anderson, president, in the chair.—A. R. Penfold: The essential oil of *Backhousia sciadophora* (N.O. Myrtaceæ) F.v.M. The leaves and terminal branchlets yielded about 0·3 per cent. of a dark brown oil, which was found to contain about 80-85 per cent. *d-a*-pinene, the remainder being sesquiterpene, sesquiterpene alcohol, with small quantities of phenol and caprylic acid ester. The constants obtained were as follo Specific gravity, 15/15° C., 0·8799-8802; opt rotation, +33·7-34·2°; refractive index, 20° 1·4704 to 1·4717; solubility in 80 per cent. alcol insoluble in 10 volumes.—A. R. Penfold and Grant: The germicidal values of the pure constitue of Australian essential oils, together with those some essential oil isolates and synthetics. Rideal-Walker tests were carried out as described previous communications, the following results be obtained: Linalool (13), linalyl acetate (5·2 coumarin (4), vanillin (3·5), isoemethone (1 methyl eugenol ether (13·5), darwinol (13), darwi acetate (3), bornyl acetate (6), amyl salicylate benzyl alcohol (5·25), benzyl acetate (2), benzaldeh (9), anthranilic acid (aqueous solution, 2, et alcohol, 12), methyl anthranilate (6·5), anethole (1 anisaldehyde (7), cinnamic aldehyde (17), ment (synthetic) (20), menthol (natural) (20), valeria acid (2), ethyl valerianate (4·5), propyl valerian (8), butyl valerianate (10), isobutyl valerianate (8 amyl valerianate (5), menthyl valerianate (3), ben valerianate (6), phenyl ethyl valerianate (4), gera valerianate (2), rhodinyl valerianate (1), citrone valerianate (2).—A. R. Penfold and F. R. Morris Notes on *Eucalyptus piperita* and its essential o with special reference to their piperitone conte part i. The leaves and terminal branchlets yiel from 2 to 2·5 per cent. of pale yellow oil possess the following constants: Specific gravity, 15/15° 0·8924-0·9016; optical rotation, −52° to −64· refractive index, 20° C., 1·4805-1·4821; solubil in 70 per cent. alcohol, 1 in 5·3 to 9 volumes; pip tone contents, 42-48 per cent. These results considerably different from anything that has pre ously been published respecting this species, and authors have come to the conclusion that there two forms of this tree. It is the first time that composition of the oil, as obtained by Surgeon-Gene White in 1788 from trees of this species grow around Sydney (considered to be the type), has b revealed, the results published by Baker and Sm from material obtained outside of the Port Jack district being from another form of the species, n termed the mountain form or variety "A." T latter has been found to yield only 0·6 to 0·8 per ce of oil containing less than 10 per cent. piperitone.

Plant Quarantines.

THE raw material of vegetable origin produced in the British Empire for consumption as food or use in industry is of infinite variety and immense value. Rubber in Malaya, tea in India and Ceylon, cocoa in the Gold Coast, jute, cotton, rice, and oil-seeds in India, wheat and fruit in Canada and Australia, all represent interests of primary importance. It is natural, therefore, to find close attention paid to safeguarding the health of the plant world throughout the Dominions and Colonies, and in recent times there has grown up a system of barriers directed against the free circulation of living plants that might serve to introduce plant pests and diseases.

It has been recognised for some time that insect, fungous, and bacterial parasites of plants are readily transported from one part of the world to another with the living host-plants on which they feed, but not so readily in any other way. Many of these organisms are delicate and short-lived, requiring food and more or less congenial conditions to enable them to survive long journeys. On that account many have remained, probably for centuries, restricted to their proper habitat —the localities in which they are "indigenous." Increased facility of communication, and the opening up of large areas to the cultivation of crops that are often exotic, have greatly increased the chances of dissemination and harmful activity of these pests. Country after country has had its lesson in the invasions of insect and cryptogamic parasites of crops, and in many cases these have been traced to introductions from overseas similar to those to which attention was directed in England by the import of wart disease of potatoes and American gooseberry mildew.

To prevent these events, or at least to reduce their frequency, a series of plant quarantines is now in force in practically all parts of the Empire. It is, in many countries, easier for an alien to land than for a living plant to be secured entry from overseas. Permits to import have to be obtained by the importer, certificates of health and freedom from danger have to accompany the consignment, and an army of inspectors is occupied in granting these certificates and in re-inspecting the plants on arrival at the ports of entry.

Such restrictions are undoubtedly hampering to the export trade in nursery stock, and even, at times, to bulk trade in agricultural produce. In 1914 an abortive attempt was made to secure international agreement in establishing a common basis for facilitating commerce in living plants, through the International Phytopathological Convention of Rome. A further attempt is to be discussed shortly under the ægis of the International Institute of Agriculture in Rome.

Advantage was accordingly taken by the Ministry of Agriculture in Whitehall of the presence of a body of Dominion and Colonial botanists and plant pathologists, who were attending the Empire mycological and botanical conferences earlier in the month, to call a conference on July 17 to consider the whole matter. This conference was attended by a number of the scientific and administrative officials responsible for the application of plant quarantine measures in England and overseas, by many botanists and mycologists, and by representatives of the trade. The opportunity was taken for a frank discussion of the various interests affected by these measures, and of the scientific bases for their application.

There is no possibility of the producing countries withdrawing altogether their restrictions of plant imports. Nevertheless, there is a strong body of opinion that total prohibition may easily be carried too far, and that prohibitions should be as few as possible and carefully scrutinised from time to time, especially so as to avoid rejection of consignments because of a small percentage of infection with some pest already widespread in the importing country. It is felt that in some cases prohibitions are inspired by distrust of the methods of disease control in the exporting country and of the efficiency of the inspecting service which certifies to the health of export consignments. Such distrust can only be remedied, on one hand, by the establishment of really efficient methods of control and inspection, and on the other, by a closer contact between the services of the different countries, such as is secured by conferences of this nature. Without mutual confidence in the plant health services, increased facilities for trade in living plants are unlikely. There is a feeling that matters are improving in this respect, and it is hoped that ultimately some amelioration of the regulations now in force may result.

The common bases for international agreement are somewhat scanty at present. Only three were formulated at the meeting, namely, (1) that every country should have the right to impose prohibition of imports with the view of restricting the risk of introducing diseases, (2) that no country had a right to ask another country to accept its exports before it had established effective plant disease control within its own borders, and (3) that no country was entitled to make a similar request unless it maintained an efficient inspection service and proper arrangements for giving health certificates. Indeed, in a general way the chief result of the conference is a recognition of the fact that a country must set its house in order before it can secure such confidence in the health of its consignments as will facilitate their admission into other countries.

Exploration in Central Asia.

Records of the Survey of India. Vol. 17: *Memoi*
Maps of Chinese Turkistan and Kansu, from
Surveys made during Sir Aurel Stein's Explorati
1900–1, 1906–8, 1913–15. With Appendices
Major K. Mason and J. de Graaff Hunter.
xv+208+30 plates (+48 maps+12 charts, se
ate). (Dehra Dun: Trigonometrical Survey Of
1923.)

THIS memoir is a record of the geograph
surveys carried out by Sir Aurel Stein du
his explorations in Central Asia, and is accompa
by 47 maps of the mountainous and desert count
north of Tibet. Stein's journeys were primarily un
taken for archæological exploration, but he made
of his opportunities for geographical surveying.
geographical world owes a debt of gratitude to S
for his surveys of these inhospitable regions; his m
will for many years to come be the main source of
geographical knowledge of this portion of Asia.
maps have been printed in colours by the Survey
India, and the memoir furnishes information as to t
history; there is an appendix on Stein's triangulat
written by Major Mason, the triangulator of the Hi
Kush, and there is another appendix on Stein's heig
by Dr. Hunter, the mathematical adviser of
Survey.

The theatre of Stein's explorations has been
great mountain horse-shoe of Central Asia, known
the Tarim basin; the Tarim river collects the wat
from the glaciers surrounding the basin, and car
them eastwards until they are choked and lost in
desert of sand. The plains of the Tarim horse-s
have an easterly opening into the Gobi desert of Chi
on the south they are shut in by the snowy ranges
Tibet, on the west by the Kashgar range of the Pam
and on the north by the Tian-Shan mountains. Ins
the basin the sand is increasing owing to the d
integration of the surrounding mountains and to t
decrease of the surrounding glaciers.

Many parts of the earth have been discovered
geologists to have undergone a slow desiccation in t
course of ages. But Stein's surveys have shown th
the Tarim basin has suffered a rapid desiccation duri
the last 2000 years. The volume of water availa
for irrigation has decreased considerably within h
toric times; the relics recovered by Stein from t
sand-buried sites of ancient towns have shown th
the latter were abandoned about A.D. 400; a long li
of ruined boundary towers has been proved by
investigations to date from 200 B.C.

It was in 1898 that Stein first approached t
Trigonometrical Survey of India and asked for th

operation in his scheme for exploring the ancient
ts buried under the sands of Tarim. The Super-
ndent of the Survey was then Colonel Gore, and
n we now look back upon the brilliant successes
h have attended Stein's three expeditions, we cannot
t feel that this first meeting between the experienced
rtier surveyor and the young ambitious archæolo-
g has led to great results. At this meeting was
nded the alliance between the Trigonometrical
vey and Stein, an alliance that has lasted without a
ak for a quarter of a century.

tein has now carried out three expeditions. On
i first expedition (1900–1901) he was accompanied
Surveyor Ram Singh, and it was on this expedition
t he discovered the extensive ruins of Niya, which
e been abandoned to the sands since A.D. 300. It
on this expedition that the peak of Kongur
(25,146 feet) was definitely proved to be higher than
th famous Mustagh Ata (24,388 feet), which had
herto been believed to be the highest point of Asia
th of the Himalaya-Karakoram mountains. In
serving the clusters of peaks round Kongur, Surveyor
m Singh made a mistake that is not uncommon in
untain surveys; he mistook the identification of
ferent peaks as seen from different places, and from
observations the Trigonometrical Survey drew the
clusion that there were two Kongur peaks, both
her than 25,000 feet; this is now known to have
n incorrect; there is but one true Kongur peak
ight, 25,146 feet), and it is depicted in the second
otograph of the Memoir. It may be recalled that
lagintweit made the same mistake as Ram Singh,
en he was observing Mount Everest sixty years ago,
l that Schlagintweit's error of identification led to
name of Gaurisankar being wrongly applied to
Mount Everest, a geographical blunder that has been
fortunately perpetuated in the new *Times* Atlas.

On Stein's second expedition (1906–1908) Rai Sahib
m Singh again accompanied him, but his health
ve way under the hardships of the work and he was
eved in 1907 by Surveyor Lal Singh. On this
ond expedition Stein's feet were severely injured by
ist-bite, and he had to be carried back to Leh in
et, where the toes of his right foot were amputated.
the third expedition (1913–1915) Stein was again
companied by Surveyor Lal Singh, who had dis-
yed exceptional zeal and fitness for surveying under
ring conditions.

The discoveries by Sir Aurel Stein of the relics of a
nished population who had had to struggle for genera-
ns against the encroachments of sand took geo-
aphers by surprise. This people, whose rivers had
en choked and whose towns had been buried, were
nd by Stein to be of a higher civilisation than that
prehistoric race which was similarly driven from its homes in Europe by the advancing glaciers of the ice-age. The entombment of the Tarim towns was not sudden like that of Herculaneum and Pompeii, but it was as complete. Stein's descriptions [1] of the ancient sites have gained for him so high a reputation as an archæological explorer that his contributions to geography are apt to be overlooked, and for this reason the publication of the new Memoir will be welcomed.

(1) ONE of the most interesting features of Prof. Juvet's book on the calculus of tensors is the preface by Prof. Hadamard. In discussing the value of a book that deals with the pure mathematical theory of tensors, Prof. Hadamard has some hard things to say about the geometrical work of recent years. Henri Poincaré once said: "The physicist expects us to solve the problems that he sets us. But in setting us these problems he pays us in advance for the service we do him in solving them. The numbers and symbols of mathematics can form an infinite number of combinations. Of all this multitude how are we to choose those that are worthy of our attention? Should we be guided solely by caprice? . . . The study of physics prevents us from losing ourselves, or, more important still, prevents our moving constantly in a circle." Prof. Hadamard thinks that this danger of losing ourselves in a mist of symbolism or of moving continually in a circle of barren argument is, in fact, a characteristic of the innumerable researches of recent years, where "the classical ideas of Gauss, Ossian Bonnet, and Darboux reappear untiringly in all

possible orders, somewhat like the performers in a circus, or like the pieces of red, green, and blue paper that our children are made to put together at school in accordance with the methods of Froebel." Prof. Hadamard concludes: "Whatever view we may hold of the value of the new hypotheses of Einstein's theory, they give geometry a new rôle, and open out for her a new lease of life . . . full of infinite fertility. . . ."

For this reason and others, Prof. Hadamard welcomes M. Juvet's book, which is indeed a very good account of the main features of the pure mathematical aspects of the geometry of relativity. The theory of vectors is developed into the theory of linear transformations of vectors, and so into the theory of tensors, followed by the theory of quadratic forms and the tensors of generalised space. The illustrations of the meaning of the quantities g in the case of two- and three-dimensional space are very helpful. There is also a good account of the theory of parallelism according to Levi-Civita and Ricci.

(2) Dr. Sheppard's aim is similar to that of M. Juvet, and he carries it out with equal success. His point of view is distinctly different, due to the fact that he is interested in algebra rather than in geometry. The book consists of two parts—the first dealing with Determinants, the second with Sets. Basing himself on the possibility that a reader who wishes to study tensor methods may be insufficiently acquainted with the necessary determinant theory, Dr. Sheppard devotes five chapters to the subject. One may reasonably suppose that a reader unacquainted with determinants will scarcely be fired with ambitious schemes like the study of tensor theory, and that, in the rare event of this happening, his eagerness is quite unlikely to survive the shock of the author's eminently and severely logical presentation of the theory. We may, however, express the belief that Dr. Sheppard's real aim is to instruct the reader who does "know" determinants, and to lead him on to the algebraic point of view as applied to tensors in the second half of the book: at any rate all readers will find the chapters on determinants a useful and interesting repetition of theory that most students know rather vaguely. There are also one or two deviations from usual notation to add zest to the repetition.

From the theory of reciprocal determinants Dr. Sheppard introduces sets, double sets, and sets of higher ranks, and thus paves the way for the second part of the book, where the sets of arithmetical quantities become sets of variable quantities and finally tensors. He adopts the Einstein contracted notation for summation, but develops a notation calculated to avoid all misconception, one feature being that Einstein's contracted notation is used o with Greek suffixes.

As already remarked, the book is algebraic, opposed to Prof. Juvet's geometrical point of vi It is true that Dr. Sheppard gives a chapter on theory of tensors as applied to relativity; but e here the aspect is analytical only, and it would possible for a reader who did not know what the the of relativity is about to read the book without suspe ing that the subject is at bottom connected w geometrical concepts.

Mention must be made of Chapter xi., which de with the use of tensor calculus in the theory statistics, based upon recent papers by the author a by Prof. Eddington.

The book is one that all English readers of mathematics of relativity should study attentively.

(3) and (4) The books by Prof. Levi-Civita and P Painlévé are not primarily concerned with relativity such. The former is a set of four lectures delive by the distinguished Italian mathematician at Ba lona in January 1921, the subjects being the probl of three bodies, the propagation of waves in wa canals, parallelism and curvature in generalised spa and geometrical optics as applied to Einstein's theo The second book is a reprint of an essay by the fam French mathematician and statesman on the axiom classical mechanics, first published in 1909, as well an essay on the principles of mechanics and causal published in 1905 in the Bulletin de la Société Franç de Philosophie. An introduction and notes on r tivity theory have been added to the present reprin

If we associate these two books with the other bo of this joint notice, it is because the chief interest Prof. Levi-Civita's book must lie mainly in the maste exposition of the theory of parallelism—one of pioneering stages in the mathematics of generali relativity, while in the case of Prof. Painlévé's book reader can at once see that the republication of th two essays was dictated and motived by the relativ controversy.

The fundamental notion of the theory of paralleli is easily seen as follows. A developable surface c sists of a number of generators. Suppose that surface is developed into a plane: two generat which then become parallel are said to be parallel the generalised sense) when the surface is not develop and the directions of any two elements of curve the developable can be related in the same w Now we can fit a developable surface to any cu drawn on any given surface, the developable touch the surface at all points of the curve: hence we define parallelism between elements of curve on a surface. Developing the analytical conditions for su

allelism and extending to any number of dimen-
ds or variables, we are led to the general theory of
eilesics, and to the equations that play so important
art in defining the motion of a particle in Einsteinian
pace.

urning now to Prof. Painlévé's book, we have to
race the remark that his attitude towards relativity
one of caution, as shown both by the present
plication and by other contributions on the subject
lsewhere. "The theory of relativity is like very
ng wine, that inebriates brains which are in-
ufficiently accustomed to the rigorous discipline of
cience": for this reason the author advises particular
ttention to the fundamental axioms of the classical
ws of mechanics, in order that he who wishes to
tudy the modifications involved in relativity theory
may at least know what is being changed! Incident-
ally, Prof. Painlévé mentions one or two common errors
in the presentation of Einstein's theory. The first is
in the suggestion that the Lorentz transformation
applies when the relative velocity of two observers is
uniform: the transformation is really laid down only
for the case where each observer's motion is uniform
relative to the "absolute" space of Newton, or to the
system of fixed stars. Another error is the statement
that, according to the theory of relativity, the laws of
Nature are the same to all observers: of course, this
is only true in the sense that certain fundamental
differential equations are satisfied independently of the
particular frame of reference, its type or its motion.
It need scarcely be said that the errors here mentioned
are almost inevitable consequences of the attempts
made to put exact mathematical statements into vague
and "intelligible" language.

Prof. Painlévé insists on the existence of *privileged*
axes of reference in actual fact: but whereas in classical
mechanics we speak of these axes as absolutely fixed,
or as moving with uniform velocity relative to abso-
lutely fixed space, in relativity mechanics these axes
are at rest in, or move with uniform velocity relative
to the totality of bodies in the universe. Axes with
origin at the centre of mass of the solar system, and
in directions fixed relative to the *ensemble* of material
bodies in the universe, Prof. Painlévé calls *Copernican*
axes: axes moving uniformly relative to these are
called *Galilean*, as is the custom in most modern
writings on the mechanics of relativity.

The author, in fact, attributes a very important
place in the evolution of the fundamental axioms of
mechanics to the influence of Copernicus. Given forces
acting on a given system of bodies will make the system
assume a configuration which at any moment depends
on these forces, on the time, and on the conditions at
zero time—the *initial conditions*. Now what are these
initial conditions? Prof. Painlévé attributes to Coper-
nicus the germ of the principle of classical mechanics,
namely, that the initial conditions comprise both
position and *velocity* of each particle of the system.

Prof. Levi-Civita's book gives also a brief account of
the optical properties of Einsteinian gravitational fields
in a manner leading up to the discussion of the light
bending in the sun's field. The other two lectures
give excellent accounts of important modern topics.
The lecture on the problem of three bodies is on the
regularisation of the problem; *i.e.* putting the equations
of motion in such a form that singularities due to the
possible vanishing of the distance between two of the
particles are made to disappear, so that the variables
can be obtained, theoretically, as functions of the time
for all values real and finite. Sundmann's fundamental
investigations are explained, and the later work by the
author and others, leading to the regularisation of the
restricted problem of three bodies, and of the general
problem in three dimensions. The lecture on waves is
one of Prof. Levi-Civita's characteristic investigations
in two-dimensional hydrodynamics, reducing the prob-
lem of the propagation of waves of permanent type
to a functional equation, with Airy's formula for surface
waves and other approximate results as special cases.

Prof. Levi-Civita's book will be of interest to all
who wish to keep abreast of modern research in
problems of applied mathematics. Prof. Painlévé's
book should be read and re-read by all students and
teachers of mechanics. S. BRODETSKY.

Theories of Colour Vision.

An Introduction to the Study of Colour Vision. By Sir John Herbert Parsons. (Cambridge Psychological Library.) Second edition. Pp. x+323. (Cambridge: At the University Press, 1924.) 25*s.* net.

SINCE all knowledge comes to us primarily through the evidence of the senses, it is unavoidable that some of the greatest controversies which have occurred in the development of the sciences should have been centred around the *modus operandi* regulating the translation of the energy of a physical stimulus into the energy of thought. It is also not surprising that the fiercest and most prolonged of these battles, not yet concluded, should have originated in connexion with the sense of sight, whereby we come most widely and most directly into relation with our external surround-
ings. These struggles have resembled no merely local disputes. They are prolonged campaigns conducted on the common borderland of three great territories; and they cannot cease until "natural" delimitations are determined as the result of statesmanship rather than as the result of militant capacity.

K-I

In the case of the colour vision controversy, the stage now attained is, on the whole, that of statesmanship, which implies the recognition of essentiality. The chief essentiality was perceived early in the contest by some of the great leaders, but the compulsion behind their conclusions was not adequately perceived until their individual work had ceased. These great leaders, working on wide lines, sought to fix the physical law which dominates visual sensation and is true irrespective of the nature of the structural details which embody it. In such a case, time gradually, and almost imperceptibly, settles the matter.

The record of this process may be traced in Sir John Parsons's work. The dominating law referred to is that of trichromasy in colour mixture. The essentiality referred to is that of trichromasy in colour perception or sensation; but there is not yet universal recognition of the *pari passu* compulsion to trichromasy, *i.e.* a triple set of freedoms only, in the physiological and the psychological processes. Yet Fechner's law is universally recognised as, and is called, a psycho-physical law —the law which relates perception to, and expresses it in terms of, the physical stimuli with regard to the results of which triple freedom is proved. The point is not merely that freedoms cannot be added, while they may be removed, in any subsequent actions having that one-to-one correspondence to precedent actions which Fechner's law asserts to hold between sensation and stimulation under fixed conditions. It is rather that the triplicity is asserted with regard to the sensations themselves. There is no room left for an independent fourth fundamental sensation whether adopted on physiological or on psychological grounds, though it may, for some purposes of description, be convenient to adopt it and use it as if it were independent. A full description cannot then be attained until the connecting linkage is at least formally taken into account.

It is intensely satisfactory to find a physiologist of Sir J. H. Parsons's standing directly speaking (p. 313) of "the trichromatism of normal colour vision, which is a fact, and not a theory." He states quite frankly his recognition of difficulty in connexion with the trichromatic, or, as he calls it, the three components theory, on two points—peripheral vision and the so-called phenomena of induction. He says (p. 231) that "we must therefore accept the theory as explaining satisfactorily *either* the phenomena of after images *or* those of dichromatic vision, but not both." But this view results from a too circumscribed estimate of what the contents of the theory are. In this particular case he speaks of necessary modifications of the theory, while all that is necessary is its legitimate development to suit new facts. The possibilities of the theory are so great that the evidence of new facts is required to] limitations upon it, and that in the very matte which he speaks. At the top of the same page he s a dilemma arising from the Helmholtzian view o way in which stimulation by light of one colour incr sensitivity towards the complementary colour. the trouble only arises because Abney's, or sir fundamentals are used; and Helmholtz's work differential sensitivity shows that these cannot b absolute fundamentals. The dilemma is really existent.

Sir J. H. Parsons's volume has filled a great gap i scientific literature, and will be indispensable as a book or book of reference even after the appear of the American edition of Helmholtz's great w The treatment which it contains of the observati and the theoretical parts of the subject is very comp and the discussions of the various outstanding v are fair and full.

The new edition is gracefully dedicated to the mer of Abney and Watson, "worthy successors of Tho Young and James Clerk-Maxwell in this field of scien

W. PEDD

Chinese Pottery.

The Early Ceramic Wares of China. By A. L. He ington. Popular and abridged edition. Pp. 169 plates. (London: Ernest Benn, Ltd., 1924.) 12 net.

THIS abridged edition of Mr. Hethering excellent volume on the early pottery porcelain of the Chinese artist-craftsmen will be comed by all those students who were unable to chase the large and profusely illustrated volume which this has been condensed. The work of redu and compression has been so skilfully carried out there is little or no loss of matter that is absol relevant, and the work here presented will serve a admirable introduction to a complete knowledge o subject, and to the more important works to whic of us must turn for the completion of the story of Ch ceramics, in all its fascinating and masterly dev ments.

The immediate purpose and scope of this little cannot be better expressed than by an extract fro preface, where the author writes: "The chapte technique has been omitted, and so have the cha on miscellaneous factories and on marks and ins tions; the present object being to confine attentic the principal features displayed by the wares wit digressing into more difficult paths." As an exa of the care which has been taken to render this abri edition usefully complete, one may mention the li "The Dynastic Epochs of China from the Mythical

ndary Periods, before 2205 B.C." (a date which rsponds roughly with that of the XVIth Egyptian sty), down to the Yüan dynasty which held sway ina from A.D. 1280 to 1368.

one could wish for a more sprightly and enter-ing guide than Mr. Hetherington through the a's of the story he sets out to unravel. Wherever ble, the history is enlivened by some amusing o of the remote past or by some shrewd hint which help to untie a knot of ancient historic fact; yet, ays there is the underlying sensibility of the serious ent. As an example of this admirable faculty we ot do better than quote a passage where the author es with the evidence we now possess that the potters he T'ang dynasty (A.D. 618–907) knew how to ufacture true porcelain with felspathic glaze.

"The advance in technical knowledge denoted by the ufacture of true porcelain as an alternative to the of pottery bodies only, and by the use of high-fired athic glazes in substitution for the low-fired lead-ilate glazes, could not have been made very rapidly vi the scientific knowledge possessed in those days China. The process must have been evolved dually by experiments conducted by competent tsmen, no doubt, but by men without full apprecia-ic of the underlying scientific principles. One feels, herefore, that the Chinese must have known how to use th simpler types of glaze for a very considerable time bere the early part of the T'ang dynasty. The geeral tendency of further research into Chinese ce.mics is to antedate rather than to postdate various tyes of ware."

he reader will welcome the terse and definite ex-pdition of the technical and artistic qualities and cracteristics of the many types of pottery and pcelain that are passed in review; no less than the csideration and valuation of the different racial inuences, Chinese and other, that brought about the fil artistic results. The simplicity of means and directness of aim manifest in the earlier wares is duly al rightly appraised equally with the glorious yet sbtle colour-qualities of the Chün *yao* bowls and bulb-ps of the Sung dynasty. In addition, the author gives ainteresting summary of our present knowledge of the fmous Ting *yao*, with its well-marked varieties of ivory-wite or rice-white glaze. Of the purple and black Tig *yao*, once so coveted by Chinese connoisseurs, no specimens can be identified in modern collections in Erope or America, and we are principally dependent f our knowledge of them on the drawings and dscriptions in the album of a Chinese collector who lied in our Tudor times.

Naturally, there is a clear, though necessarily smmary, account of the renowned Céladon wares, which seem to have been more largely exported at the tne of their manufacture than any other variety of porcelain. In addition, the history of the Tz'ŭ Chow wares—made at what must be the oldest pottery-centre in the world that is still in active operation, for it dates back to the Sui dynasty (A.D. 589–618)—has its puzzles for the collector of to-day, for, as is well said, "It is extremely difficult to determine which specimens are of Sung origin and which of Ming or even later date."

In the final chapter we have an account of the Chien wares, which have only been recognised as a distinct class in what we may call recent times. The fascinating glazes which are usually associated with these wares and are distinguished on account of their markings as "hare's fur" or "partridge markings," are usually applied so thickly that in the majority of examples they form a dark pool in the inside and thick running lines with a terminal blot on the outside of the vessel to which they are applied. These special glazes appear to have been most extensively used in the decoration of small bowls which ritual use long ago prescribed for the "tea ceremonial" or tea contests. The Chinese have always been inveterate gamblers, and in this particular "gamble" the idea was to pit the cup of this type owned by one connoisseur against that owned by another to decide which would retain moisture longest. As Mr. Hetherington says, "The game seems a curious one to Western minds, but, after all, roulette has no more claim as a sensible method of gambling." The tea ceremonial was introduced into Corea and Japan, and with it the bowls and other apparatus of the game. The Japanese have made many varieties of these bowls, some of which are difficult to distinguish from Chinese specimens; though any one who collects with an eye to beauty alone may be delighted to treasure a Japanese specimen for its æsthetic worth.

A word must be added in praise of the illustrations, for though there is only one coloured plate (an extremely beautiful one), the half-tone illustrations convey an excellent impression of the objects they represent, and will greatly aid the student in the identification of specimens.

WILLIAM BURTON.

Diseases of Wild Animals in Captivity.

Disease in Captive Wild Mammals and Birds: Incidence, Description, Comparison. By Dr. Herbert Fox. Pp. vii+665+91 plates. (Philadelphia, London and Chicago: J. B. Lippincott Co., 1923.) 60*s.* net.

ALTHOUGH it is the custom in most zoological gardens to keep a record of all post-mortem examinations, this is the first time an attempt has been made to correlate the results and place them in a compact form before the medical and veterinary professions.

Dr. Fox has held the post of pathologist at the Philadelphia Gardens for the past twenty years, and during that time has had the opportunity of making post-mortem examinations on 1860 mammals and 3505 birds. In addition to this he has also studied the living animals, and has been able to apply his pathological findings to the diagnosis, treatment, and prophylaxis of disease in general. The result of his work has been of extreme practical value in the management of the Philadelphia Gardens; epidemics have been arrested by scientific disinfection, and certain diseases, such as spiropteriasis in parrots and tuberculosis in monkeys, have been entirely eliminated. In order to prevent the introduction of tuberculosis, every new arrival before being placed in the collection is subjected to the tuberculin test, and the variations of temperature during the ensuing forty-eight hours are recorded. In healthy animals there is no reaction; in tuberculous animals there is usually a definite rise in the first twelve hours. No animal showing a positive reaction is placed on exhibit.

Among other communicable diseases investigated, the "jaw disease" of kangaroos has been made the subject of special research. The causative organism of this disease was found to be one of the Mycobacteriaceæ, which was cultured successfully and a vaccine prepared. It was found to be new to science, and has been named *Nocardia macropodidarum*. From experiments upon laboratory animals with cultures of *N. macropodidarum*, it would appear that the disease is transmitted with difficulty. As it is always found associated with a small Gram-negative bacillus, it is possible that the bacillus is a necessary factor in the production of the disease.

The section on the incidence and significance of animal parasites, by Dr. F. D. Weidman, emphasises the value of zoological gardens in general as a field for research on this subject. Tables showing the pathogenicity and frequency in the various orders are given, and various methods of treatment and prophylaxis are suggested.

The tables giving the relation of diet to disease show that birds and mammals which live on a mixed diet of plant and animal tissue are less liable to disease of the alimentary tract than those which are entirely carnivorous or herbivorous. The percentage of thyroid disease and rickets was highest among the Carnivora.

Neoplasms, both benign and malignant, are treated at some length, and valuable tables are given, showing the type of growth, organ of origin, relation to sex, duration of captivity, metastases, and order of animal affected. Neoplasms were found to be commonest among the Rodentia, Marsupialia, and Carnivora, and rare among the Primates. The main organs affe were uterus, liver, thyroid, and mammary glands.

The book is well illustrated with photograph microscopical and macroscopical specimens of pa logical changes, in addition to numerous intere and valuable statistical tables dealing with th cidence of disease.

In the foreword, Dr. C. B. Penrose, the presi of the Philadelphia Zoological Society, makes s general remarks on some of the problems which in relation to the keeping of animals in captivity, the various mental perversions which are com among them, some of which are akin to prison psych in man. Diseases of the central nervous system special senses are dealt with in a special sectio are the diseases of all the other organs of the body

There is no doubt that this work, which is essent a pioneer effort, should be read by every compara and human pathologist. By those who are conce in the management of living animals in captivit will be found to be a mine of valuable information

Our Bookshelf.

(1) *Physics.* Vol. I.: *Mechanics, Heat and Engines.* By W. J. R. Calvert. (Science for Series.) Pp. x+260. (London: John Mur 1924.) 3*s.* 6*d.*

(2) *A Text-Book of Physics: including a Collectio Examples and Questions.* By Dr. W. Wat Eighth edition, revised by Dr. Herbert Moss. xx+976. (London: Longmans, Green and 1923.) 16*s.* net.

(3) *Thermodynamique: Énergétique: Théorie cinét des gaz* (*Cours professé à la Sorbonne*). Par I A. Leduc. Pp. iii+333. (Paris: Gaston D 1924.) 25 francs.

ACCORDING to Dr. George Saintsbury, "A review is a thing addressed to the general body of educ people, telling them whether it is or is not worth t while to make further acquaintance with such-and-s a document purporting to bear their address." I of the three books included in the present notice ha own merits, but each is addressed to a special clas reader.

(1) The book by Mr. Calvert, who has been a sci master at Harrow since 1909, forms the first vol on physics in the "Science for All" Series. I intended for pupils up to the age of, say, sixteen, are taking a course of science as part of their gen education. For such students the book is a n admirable one, the interest, both from the scientific the literary point of view, being skilfully sustai throughout. The ideas of work and energy form main theme, applications being made to the subj of hydrostatics, statics and dynamics, and heat. I preface of unusual interest Mr. Calvert discusses principles underlying the teaching of science in earlier stages of a general education. Such teach should give the pupil some idea of the aims of scie

the kind of problems with which it deals; a ledge of some of the broad fundamental principles; ome insight into scientific method.

Dr. Watson's "Text-Book of Physics," intended nore advanced students, is too well known to re more than the briefest notice. In the revised ion considerable additions have been made to ir the work into line with recent progress, especially te subject of electricity.

Prof. Leduc reproduces in this volume a course out thirty advanced lectures on heat delivered at e Sorbonne. He remarks that amongst his hearers te physicists are in the minority; nevertheless, ightly considers it desirable to consider his subject o the point of view of research, discussing the methods d results of recent investigations, including those as himself undertaken. Stress is laid on the cy of the numerical results, and one of the luable features of the work is the information (not ys easily accessible to the student), which is supplied the quantitative values arrived at in the most t determinations of thermal constants. The book ded roughly into four parts. The first deals with ral questions connected with thermometry, calori- y, and equations of state. The second and third are devoted to the general principles and applica- of thermodynamics respectively, whilst the very fourth part deals with the kinetic theory of gases. I a few cases the historical references are not plete or accurate. It is probably useless to protest gainst the constant use of "la loi de Mariotte," but we cannot have Boyle's law, we would enter a plea some mention of Joule's law as to the additive re of the specific heat of compounds. Again, 'Expérience classique de Tyndall" (p. 204), in which a ded wire cuts through a block of ice, is really due Lord Kelvin's nephew, Dr. J. T. Bottomley, as is ted in "Heat a Mode of Motion," p. 150 (1887). In pite of some minor defects the book is an excellent on and an English translation might well appeal to a large number of students. H. S. A.

An Elementary Treatise on Frequency Curves and their Application in the Analysis of Death Curves and Life Tables. By Arne Fisher. Translated from the Danish by E. A. Vigfusson. American edition. Pp. xvi+244. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1922.) 20*s.* net.

THIS book under notice is divided into two parts; the first gives an account of the Gram-Charlier curves and curve fitting taken, in places verbatim, from the author's "Theory of Probability" and the second part deals with a method of estimating rates of mortality from statistics of the numbers of deaths from various causes at each age. The object in finding a method which will enable the statistician to dispense with censuses, or exposed to risk, when estimating mortality is that in some cases only the deaths are known and in others the trouble and expense of obtaining a census, or exposed, are considerable. The author's method is to choose a system of frequency curves based on the hypothesis that the distribution of deaths according to age from certain groups of diseases can be made to conform to those assumed curves; proportional death rates are calculated for each age (or groups of ages) according to the grouped causes of death. From these figures, by a lengthy arithmetical process, the number dying in a stationary population is reached, and this leads to the rates of mortality. The method is interesting and in some cases it gives results which are in close agreement with those obtained by the usual methods, but, in other cases, the examples given seem to imply that there may be considerable errors in the result, although in these cases a modification of the groupings of deaths might lead to improvement. It would appear from *a priori* considerations that, in some circumstances, it must be impossible to obtain a satisfactory result from deaths alone (compare, for example, two experiences having rates of mortality such that the rates by one are equal to r times the rates of the other at all ages).

The book has many defects; some of them are no doubt due, as is suggested by the author in his preface, to the original Danish MS. of the second part of the book having been translated by an Icelander and to the composition and proof reading having been done by a Copenhagen firm; but the explanation affords little comfort to the troubled reader. Possibly the international nature of its origin accounts for the fact that the book, which is dated 1922, has only recently reached us. Another point open to criticism is the omission of a clear explanation at the beginning of the second part of the theory and assumptions on which the author intends to base his construction of mortality tables, so that a reader has more difficulty than is necessary. We think that the author would have been well advised if he had set out some, at any rate, of the difficulties and criticisms that would naturally occur to his readers and how he would propose to answer them.

The idea and the method are interesting; but the evidence in favour is not conclusive and we are afraid that the remark in Prof. Raymond Pearl's introduction that "it may fairly be regarded as *fundamentally* the most significant advance in actuarial theory since Halley" is an unfortunate over-statement.

Smithsonian Institution. United States National Museum: Bulletin 82. A Monograph of the existing Crinoids. By Austin H. Clark. Vol. 1: The Comatulids. Part 2. Pp. xxv+795+57 plates. (Washington: Government Printing Office, 1921.)

RARELY can there have been produced a work so thoroughly deserving the title of Monograph as this vast production of Dr. Austin Hobart Clark's. The first part, of 387 pages, issued in 1915, dealt with some general principles and began the account of the anatomy; it is unfortunate that the pre-occupations of war prevented it from receiving adequate notice. This second part, continuing the description of the comatulids or feather-stars, completes the details of their anatomy, family by family and species by species. There follows a summary of the development, again with reference to every species in which any larval stage is known. An interesting chapter is that on the various habitats of the littoral crinoids. There follow notes on the habits of Antedon, and then a long, well-documented list of parasites and commensals. Next are brought together the scattered observations, experimental and other, made on the tropisms and relations to environment of numerous comatulids.

The chapter on the colour of crinoids includes the stalked and sessile forms as well as the unstalked. The part ends with a section on the economic value of the recent crinoids; this is confined to their sale as curios, for, we are told, they serve no useful purpose; they are not even eaten by any animal that serves as human food. In this respect it is probable that the recent crinoids have acquired a securer footing than some of their large-bodied ancestors.

These two large books, though they contain only "introductory matter" to the systematic descriptions, already furnish a corpus of nearly every observation ever made on these beautiful creatures, and reference is facilitated by full tables of contents and indexes. Although a great deal of the work is based on Dr. Clark's own observations, especially concerning the skeletal and muscular anatomy, it does not profess to give new facts or original theories. That in no way lessens its great value to the worker, who will also find his wants attended to by various keys and by comparative diagrams. He will be grateful to Dr. Clark and will marvel at the energy and perseverance that have brought him so far along a laborious road.

The Subject Index to Periodicals, 1917–1919. Issued by the Library Association. L: List of Periodicals Indexed and Author Index. Pp. ix+103. (London: Grafton and Co., 1924.) 21*s.* net.

THE alphabetical index of names of authors of articles included in the various Subject Indexes to Periodicals issued by the Library Association for the period 1917–1919 has now been published. The index contains more than 20,000 names of authors, with the sections of the Index and the headings under which the titles of their papers are registered. It is estimated that, on an average, each author has published two papers, so that the total number of papers indexed for 1917–19 will be about 40,000. Those who possess the valuable Subject Indexes already published will be able through this author index to find a paper when they have forgotten its title although they remember the author's name. The abbreviations for 477 periodicals used in preparing the indexes for 1917–19 are also given.

The headquarters of the "Subject Index to Periodicals" were transferred to the National Library of Wales, Aberystwyth, in January 1921. The access to periodicals in this Library has been of great assistance to the editors in preparing the indexes. The editors record the voluntary help they have had from some forty-eight libraries in Great Britain and from a number of private contributors. While expressing its grateful thanks to all who have helped in the undertaking since its beginning in 1915, the Library Association makes a strong appeal for assistance to those librarians who have hitherto held aloof from active co-operation in the work.

It is obvious that the value of the Index depends upon its completeness; although up to the present time some 575 periodicals have been examined, some of the libraries that have not yet taken part in the work may very well have on their shelves other periodicals containing relevant matter. We would urge any such libraries to consider whether they cannot arrange to assist in the future.

Laboratory Experiments in Chemistry: to accom Black and Conant's "Practical Chemistry." N. Henry Black. Pp. x+167. (New York: Macmillan Co.; London: Macmillan and Co., 1923.) 5*s.* net.

THE author of this small work can be congratul upon having written a really practical text-book w is much superior to most of those now used in G Britain. Its chief feature is absolute clarity of pre ation; no pupil should go wrong if he follows faith the directions given, and if he tries to answer numerous questions interpolated throughout the he will exercise his intelligence as well as his fingers his capacity for obeying instructions. Those prefer the strictly heuristic method of teaching probably not regard with favour a book of this k but they would find it very useful if—as is usually case—they are expected to cover a lot of ground a large class in a limited time. Other valuable feat are the optional work given after each experim and, near the end of the course, some elemen lessons in applied chemistry. The present writer given some of these experiments to his pupils and testify to their value, not only in imparting knowl but also in stimulating interest. Some minor poin criticism will doubtless suggest themselves to e teacher, but these are negligible in comparison the excellence of the work as a whole. Uncons humour, too, is not often to be found in a school book, but if the reader will refer to the second sent on page 1 of this book and then glance at the illu tions on the frontispiece opposite, he will learn the homely test-tube, beaker, crucible, etc., are an the "less familiar" pieces of apparatus. We wo what are the more familiar pieces of apparatu American schools?

Principles of Electric Motors and Control. By Go Fox. Pp. xiv+499. (London: McGraw-Hill lishing Co., Ltd., 1924.) 17*s.* 6*d.* net.

MOST books describing electric motors and contro are written mainly from the point of view of the signer, that is, from the point of view of the m facturer. The number of operating engineers, how is much larger than the number of designers, and fa application, as the author points out, can nullify design. This book is intended for students and those interested in the selection, application, purch and sale of electric motors and controllers. The cussions are simple and practical and will be e understood by the engineer. Although many gr are given, vector diagrams and higher mathem have been rigorously excluded. The control diagr all conform to standard American practice, but practice in Great Britain is much the same. A full bibliography is given.

The book will be found helpful both to the prac and theoretical electrical engineer. The latter will in it diagrams which illustrate excellently prac applications of known theoretical principles with w he is familiar. For example, a clear diagram is g of the principal connexions for converting from system of supply to another of different frequenc constant power.

himæras Dire: Transplantation of Heads of Insects.

ITH some astonishment I notice my friend, W. T. Calman, agreeing with the German authors as Blunck and Walter Speyer in his letter to URE of July 5, p. 11, entitled "Chimæras Dire," vich is written with much sarcastic humour, but ite knowledge of the subject. The title itself is nleading. Walter Finkler has never claimed to e produced Chimæras in adult insects, a term ifying in biology "simultaneous development of ts compounded from tissues of different species o races)"; he has merely studied the possibility of relantation of heads and described the results treof. He has neither written that "The head of a bivorous water-beetle persuaded a carnivorous dy to be content with, and seemingly to digest, a vetable diet," nor that "a Dytiscus strove to derate the colourings of its wing-cases to suit the ser tastes of its new Hydrophilus brain." The ny part of Finkler's work referring to nurture (*Archiv f. mikrosk. Anatomie u. Entwickl.mechanik*, xix., 1923, p. 113) alludes to the passage of coloured ae through the re-established connexion between th cut ends of the œsophagus in *homoplastic* experiments on the replantation of Hydrophilus-heads, while the assumption of a darker hue after heteroplastic replantation of a Hydrophilus-head to a Dytiscus-body refers to the yellow crossbars of the thorax in the swimming beetle (pp. 127-128), a result Finkler ascribes to the influence of eyesight, but that can perhaps be more readily explained on the assumption of tyrosinase diffusing from the head to the thorax.

Dr. Calman's sentence, "a male head led a female ly into unwonted perversities," will, I am afraid, do produce a wrong impression of Finkler's observations. Finkler's xenoplastic experiments on the exchange of heads between a male and a female Hydrophilus were conducted to see if the reproductive glands have any influence on the sexual instinct as displayed by the head in the antennal play of the male (and the several reflexes of the legs inspired by the œsophageal ganglions of the intact imago). The result was that no such influence could be detected (p. 124). The male head kept its usual reaction towards the female, and the female head did not acquire this character when transplanted to a body of opposite sex, quite in agreement with the many experiments on other insects, where removal or even heterological exchange of the reproductive glands in larvæ always failed to display any change in the secondary sexual characters of the imago.

As to the knowledge of Drs. Blunck and Speyer, already known by a long series of anatomical and biological researches on the very water-beetles that were among the chief of Finkler's *corpora vilia*," of the physiology of these insects, I have just stated an example of it: they have maintained that a Hydrophilus with Dytiscus-head could never live in water, because the former needs its feelers for respiration. Any one can easily convince himself of the fallacy of this belief, dating from an unlucky fabulation of Kitzsch (1811!) and repeated, it is true, in all treatises on the physiology of these beetles since his time. It is only necessary to amputate both antennæ of some Hydrophilus and keep the beetles as usual in water with some algæ. No inconvenience will befall them on account of this loss. I have a paper in the press on this subject for the *Zoologischen Anzeiger* which is to appear shortly, discussing the various criticisms of Finkler's experiments by several authors in Germany. I need not, therefore, go into further details now.

I should, however, like to add that Finkler has not "ignored requests to produce his chimæras, alive or dead, for investigation by others." His transplantations were produced alive at the meeting of the zoological section of the Zool. Bot. Society of Vienna on November 11, 1921, for general inspection, and some dead specimens were handed on to Dr. Boulenger (has not Dr. Calman had the opportunity of seeing these himself as an "exhibit at a Royal Society soirée"?); the total preparations of the beetles, of which Finkler's Plate IV. gives but a poor impression, are in our Museum and hundreds have seen them. Wit is appropriate "in the pages of *Punch*"—but in the pages of NATURE we should try to keep to strict truth.

As to Mr. J. T. Cunningham's recent note (NATURE, July 26, p. 124) on "Transplantation of Heads of Insects," I am puzzled if it is meant as a joke or is the author really used to making his experiments on *five* individuals? (By the way, I am sure he cannot have read Finkler's paper, or he would have known that Finkler has attempted the transplantation of the *head alone* in the meal-worms without success.)

HANS PRZIBRAM.

The Vivarium,
Vienna II. Prater.

Radial Velocities and the Curvature of Space-time.

THE question of the reduction of the Doppler effect from the earth to the sun, or conversely, raised by Prof. Eddington in NATURE for May 24, is completely settled in my letter of May 10, which was published in NATURE for June 7, p. 818.

In his letter, however, Prof. Eddington mentions another point, the possible occurrence of an "imaginary star constant v_0" in

$$D^2 = r^2/R^2 + v_0^2/c^2, \quad . \quad . \quad . \quad (1a)$$

which requires an explanation.

The actual position is this. With some R-value, derived from previous material, a new object of estimated distance r may show an effect $|D|$ smaller than r/R. Then (1a) calls for a negative v_0^2 or an imaginary v_0. What is the meaning of such a value? Simply, that the orbit *does not pass* through O, the sun, but ends at some perihelion distance $r_0 = R\sigma_0$, where the motion is reversed. Such radial motions are possible in de Sitter's world. Even then the analytical form (1a) may be retained, provided we remember that v_0^2/c^2 is to be replaced by $-\sigma_0^2$. In fact, by the equation of motion (NATURE, March 8)

$$\frac{R}{c}\frac{d\sigma}{dt} = \pm \cos\sigma\sqrt{1 - \cos^2\sigma/k^2} = \pm\frac{v}{c},$$

or by the original meaning of the constant, $k = \cos^2\sigma c dt/ds$, we have

$$k = \cos^2\sigma/\sqrt{\cos^2\sigma - \dot{v}^2/c^2} = \text{const.}$$

If the star passes through the sun, $v = v_0$ for $\sigma = 0$, and $k = (1 - v_0^2/c^2)^{-\frac{1}{2}}$, and the formula

$$D = k[1 \pm \sqrt{1 - \cos^2\sigma/k^2}] - 1 \quad . \quad . \quad (1)$$

reduces approximately to (1a). But if it does not

pass through the sun, we have $v=0$ for $r=r_0$, so that $k=\cos\sigma_0$, and (1) becomes, for small σ_0, σ,

$$D^2=\sigma^2-{\sigma_0}^2=\frac{1}{R^2}(r^2-{r_0}^2). \quad . \quad . \quad (1b)$$

If the object, no matter how distant, just passes through its "perihelion" or nearly so, we have a nil-effect or a small effect. Such cases may be rare (as *e.g.* that of N.G.C. 6626), but are possible and well provided for by the general formula (1). This removes every difficulty. At the same time we see that, in a correlation graph, the observed points r, $|D|$ need not lie all above a certain line, but may as well fall below it. They should only show a tendency of crowding along it, on either side, gathering pre-eminently, but not exclusively, in the first and the third quadrants (NATURE, June 7, p. 819, Fig. 1). Such a tendency is shown, by the points thus far available, markedly enough. These relations and formula (1*b*), a supplement to (1*a*), are discussed in my second *Phil. Mag.* paper now in the press. There also the desirable extension of the formula from radial to *any* inertial motions is given. If $r_0=R\sigma_0$ and $v_0=c\beta_0$ be the distance at and the velocity of passage through the perihelion, the result is, rigorously,

$$D=\frac{\cos^2\sigma/k}{1\mp\sqrt{1-\frac{\cos^2\sigma}{k^2}\left(1+\frac{p^2}{R^2\sin^2\sigma}\right)}}-1, \quad (2)$$

where

$$k=\cos^2\sigma_0/\sqrt{\cos^2\sigma_0-\beta_0^2}, \quad p=R\beta_0\sin\sigma_0/\sqrt{\cos^2\sigma_0-\beta_0^2},$$

and approximately, to all purposes,

$$D^2=\left(1-\frac{{r_0}^2}{r^2}\right)(\sigma^2+\beta_0^2), \quad . \quad . \quad (2a)$$

of which (1*a*), (1*b*) are but obvious special cases. The statistical formula, (2) (NATURE, June 7, p. 818), now becomes $R^2=\frac{2}{3}({r_1}^2-{r_2}^2):(D_1^2-D_2^2)$, and, when applied to all thirteen objects there tabulated, gives $R=7{\cdot}2\times10^{12}$ astr. units. Details are given in the last-mentioned paper. LUDWIK SILBERSTEIN.

Rochester, N.Y., July 5.

Growth-rings of Herring Scales.

WHILE engaged upon work on herring scales at the Ministry of Fisheries' Laboratory at Lowestoft in 1922 and 1923, I made several discoveries regarding the so-called "winter rings," and the comparative growth-rates of scale and fish. These discoveries appeared to me to be of sufficient importance to be brought forward for discussion at a meeting of the Herring Committee of the International Council held at Edinburgh in June 1923, at which I offered a theory of age-determination alternative to the Norwegian theory.

At a later meeting held at Christiania in June 1923, the Herring Committee rejected my theory and adopted the Norwegian theory as a working hypothesis. To this resolution I was a subscriber with some misgivings. In the light of further research, however, I am compelled to revert to my former position, and, while, in accordance with the resolution of the Herring Committee, the Norwegian theory is accepted by the Ministry of Fisheries as a working hypothesis, it has been thought desirable that I should be given an opportunity to state publicly the main facts on which my theory is based, since these have not yet been published. They are as follows:

(1) While in the case of young herrings the number of "winter rings" is the same on all normally developed scales, in the case of older fish there is considerable variation in their number. The greatest numbers appear on the large scales from the forepart of the body (position A), which are used by the Norwegians for age-estimation, while the smaller numbers of clear and easily-read rings appear on scales from near the edge of the dark dorsal pigment and below the posterior end of the dorsal fin (position B). Photos, Fig. 1 and Fig. 2, are of scales from two English fish of 27 cm. in length, landed at Lowestoft. Fig. 1 is from position A and Fig. 2 from position B.

(2) The proportionate growth-rates of scale and fish are similar on scales from regions A and B in the case of small herrings, but increasingly dissimilar as larger and larger fish are taken. Thus, in large fish of which the scales from position A are very ringy (usually known as "old" fish), either the ringy scales have grown disproportionately fast or the scales from position B disproportionately slow in the later life of the fish. That the differences

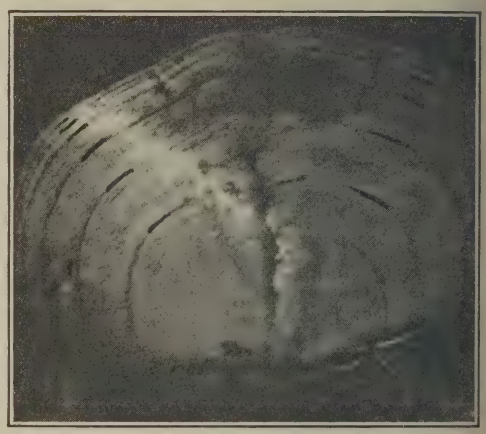

FIG. 1.—Showing six rings traceable all round the striated portion.

in the "calculated growth" are significant is obvious from the following examples:

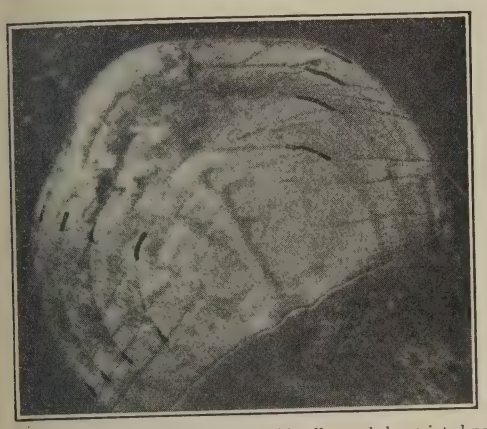
			Calculated Growth. Scale from Position (A).	(B).
(1) Shields fish .	37 cm.	1st year	10·5	12·6
		2nd ,,	20·3	23·6
		3rd ,,	27·2	30·4
(2) Norwegian .	34 cm.	1st ,,	8·0	9·8
		2nd ,,	15·1	16·9
		3rd ,,	22·6	25·5
(3) Norwegian .	34 cm.	1st ,,	6·7	8
		2nd ,,	12·1	14·1
		3rd ,,	21·3	23·8
(4) Norwegian .	34 cm.	1st ,,	6·4	8·8
		2nd ,,	11·0	13·6
		3rd ,,	13·8	17·1

This discrepancy in calculated growth is due to difference of growth-rate taking place mainly in the later part of the herring's life, as may be seen by assuming any length, say 15 cm., for the length of the fish (say No. 4) at the formation of the 3rd ring and calculating the two first years' growths from the two scales, giving

	Scale A.	Scale B.
1st year . .	7·1	7·7
2nd ,, . .	12·0	12·0

This is very significant, considered in relation to the so-called "phenomenon of decrease of calculated growth-rate with age," which is ascribed by the Norwegians to the influence of migration, the larger fish of each year-class joining any shoal of large fish first.

) The groupings of rings on the outer part of h scale of large herrings. In a large number of as of ringy scales there is a tendency for the inter rings" to get closer and closer as we go rn the centre of the scale, until they become very rvded at a certain point; after which they widen n again get closer and closer, and again become rvded. Fig. 3 exemplifies this phenomenon. If h rings are read in groups, instead of singly, an



ig. 2.—Showing only four rings traceable all round the striated portion.

eimate of age is arrived at, differing widely from tat based on reading of single rings—in the present se 5 years instead of at least 14 years, the inner oup under a high power being seen to consist of aout 5 rings, and the outer of about 6 rings, and the tree rings inside these two groups being read singly, d the sub-surface phenomena occurring inside these ngs would not be considered as "annual rings" h any scale-readers.

(4) The existence of rings in the outer part of the

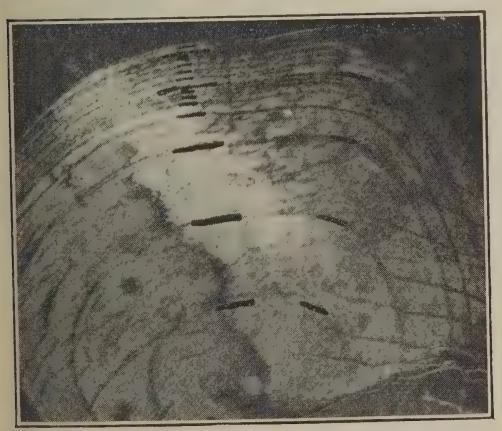


FIG. 3.—Showing three single rings and two groups of rings.

ale having stronger optical value than neighbour-ng rings, but similar optical value to the first 3 or winter rings. These strong or "α" rings can ften be traced out into the exposed part of the ale. If only these "α" rings are recognised as inter rings the age-estimate is of course lower han in the reverse case.

The above phenomena form the main basis of ny disagreement with the Norwegian theory. To ention further evidence for my views or to describe ny alternative theory would extend this beyond he bounds of a letter, but such evidence exists and will be laid before any workers interested in the matter. The scales from which the photos, here reproduced (Figs. 1-3), were taken, and many others, are also open to inspection.

Fisheries Laboratory,
Lowestoft, July 17.

The Band Spectrum of Boron Monoxide.

IN two recent letters to NATURE (May 24 and 31) Mr. W. Jevons has questioned the adequacy of my evidence as to the oxide origin of a band spectrum which he had previously ascribed to boron nitride.[1] In his second letter he reports that these bands are absent from the spectrum of the discharge through a mixture of BCl_3 and O_2, although the ordinary boric oxide bands are present. This he considers convincing evidence against BO as the emitter of the bands in question. In view, however, of evidence outlined below, a full account of which will appear probably in the *Physical Review*, there seems little room for doubt that the bands are really due to BO and not to BN. The other oxide bands may then be ascribed, as in the past, and in accordance with their complex character, to B_2O_3.

When generated by the reaction of BCl_3 with active nitrogen, the intensity of the BO bands shows a maximum when perhaps 0·5 per cent. of oxygen is present. If the nitrogen is purified beyond this point, using phosphorus, its degree of activation, as gauged by the intensity of the α bands of the afterglow, is increased markedly, finally approaching asymptotically an upper limit. Unlike the BO bands, the SiN bands, obtained by using $SiCl_4$ instead of BCl_3, are stronger the less oxygen is present, and are practically extinguished by the amount of oxygen most favourable for BO. These facts appear to disprove Mr. Jevons's suggestion that the weakening of the BO bands in very pure nitrogen is due to a decrease in its activity when the oxygen is all removed. Probably, if this stage of purification was approached, phosphorus vapour replaced oxygen as a catalyst.

When the BO bands are at their strongest, the yellow of the α bands and the blue of the β bands of active nitrogen are roughly equal in intensity. Lord Rayleigh has shown[2] that the β (and γ) bands are due to the presence of oxygen, probably as NO. Prof. R. T. Birge has concluded[3] that the α bands are emitted by (metastable) excited N_2 molecules; also (private communication) that the β and γ bands are due to NO.[4] The formation of the emitters of the BO bands may then proceed somewhat as follows, denoting an electronically excited molecule by an accent (′):

(1) $BCl_3+N_2' \rightarrow BN+NCl_3$. (2) $BN+NO' \rightarrow BO'+N_2$.

Or, the formation of BO′ may be more direct; in any case, some BN is probably also formed,[1] but apparently gives no spectrum.

In repeating Mr. Jevons's recent experiments, I have found the B_2O_3 bands best brought out with a very large excess of oxygen over BCl_3. Under these conditions the ratio of excited BO to excited B_2O_3 molecules present and emitting at any moment may well be negligibly small, in view of the chemically highly unsaturated character of BO. In active nitrogen,

[1] W. Jevons, Roy. Soc. Proc. A, 91, 120-34 (1915).
[2] Roy. Soc. Proc. A, 93, 254 (1917).
[3] *Phys. Rev.*, 23, 295 (1924).
[4] E. P. Lewis (*Astrophys. Journ.*, 20, 49, and 58 (1904)) has shown that the γ bands are, without much doubt, due to NO; and Birge finds that the β and γ bands have a common final state. Also, their simple structure indicates a diatomic emitter.

however, consisting of a small proportion of N_2' and NO′ molecules in a medium chiefly of unexcited and so inert nitrogen, and with no continuous exciting discharge, this ratio may well be reversed, especially in view of the probable mode of formation of BO.'

In some experiments with a carbon arc,[5] the anode of which contained BN, B_6C, or B_2O_3, I have found that in all three cases the BO (and the B_2O_3) bands appear, in moderate intensity, when an atmosphere of oxygen or air is used, but that they are completely absent in nitrogen. In the latter case BN is doubtless formed, but does not emit a spectrum. No doubt B_2O_3 is partly dissociated into BO at the high temperature of the arc. In the lower temperature of the flame only the B_2O_3 bands are known to occur.

The final piece of evidence is the very close agreement of the vibrational isotope effect with theory for BO, and its definite disagreement for BN. In view of the strength of the theory, this by itself makes BO very probable. If the bands were due to BN, the agreement of experiment with theory would become qualitative only; and if this were the case, the chance is very small that the deviation of the theory from quantitative correctness would be just such as to correspond to an exact but illusory quantitative agreement for BO. The following empirical equations represent within experimental error the positions of all the measurable BO band heads:[6]

$$B^{10}O:\ \nu_\alpha = \begin{Bmatrix} 23652{\cdot}2;\ 23638{\cdot}9 \\ 23526{\cdot}0;\ 23512{\cdot}7 \end{Bmatrix} + 1285{\cdot}6n' - 11{\cdot}7n'^2 - 1926{\cdot}8n + 12{\cdot}21n^2$$

$$B^{11}O:\ \nu_\alpha = \begin{Bmatrix} 23661{\cdot}6;\ 23648{\cdot}3 \\ 23535{\cdot}4;\ 23522{\cdot}1 \end{Bmatrix} + 1247{\cdot}9n' - 10{\cdot}6n'^2 - 1873{\cdot}2n + 11{\cdot}68n^2$$

Ratio: (*Difference* = −9·4) 1·0302 1·104 1·0286 1·045

$$B^{10}O:\ \nu_\beta = 42874{\cdot}6 - 0{\cdot}19nn' + 1304{\cdot}6n' - 10{\cdot}43n'^2 - 1927{\cdot}9n + 12{\cdot}66n^2$$

$$B^{11}O:\ \nu_\beta = 42880{\cdot}9 - 0{\cdot}17nn' + 1268{\cdot}8n' - 9{\cdot}98n'^2 - 1872{\cdot}9n + 11{\cdot}84n^2$$

Ratio: (*Difference* = −6·3) 1·0282 1·045 1·0294 1·069

For the coefficients of the linear terms, the theoretical ratio is 1·0292 for BO and 1·0276 for BN; for the quadratic terms, 1·0593 for BO and 1·0560 for BN. The mean of the four experimental values is $1{\cdot}0291 \pm 0{\cdot}0004$ for the former, $1{\cdot}066 \pm 0{\cdot}010$ for the latter.—The coefficients of n and n^2 indicate a common final state for the α and β systems.

A remarkable feature of the BO bands is the non-coincidence, for the bands having the vibrational quantum numbers n and n' both zero, of corresponding heads of the two isotopes. For the centres of these bands an approximate correction, based on measurements of band structure, increases the differences recorded above to −10·0 and −7·2 for the α and β systems respectively. According to the theory as now accepted, these corrected differences must represent electronic isotope effects, of much greater magnitude than have been found in line spectra. Since this is highly improbable, the following alternative explanation is decidedly to be preferred. If one assumes that the true values of the vibrational quantum numbers are not n and n', but each $\frac{1}{2}$ unit greater, the apparent isotope effect for the true vibrational zero point is reduced to −2·2 for the α and +2·4 for the β system. These differences are now small enough to have resulted from inaccuracies in the determination of equation coefficients. It is then probable that the minimum vibrational energy of BO (and doubtless of other) molecules is $\frac{1}{2}$ quantum. In the case of molecular rotational energy, the necessity of using half quanta is already well established. Analogous relations appear in line spectra; *e.g.* Heisenberg[7] has successfully used half-integral radial and azimuthal quantum numbers in explaining structure and Zeeman effect of doublets and triple

ROBERT S. MULLIKEN,
National Research Fellow
Jefferson Physical Laboratory,
Harvard University, Cambridge, Mass.

[5] Similar experiments by Jevons (*l.c.*) on a boron arc were inconclusive, although favouring the nitride origin of the BO bands.

[6] It can be shown that no appreciable error is introduced here in the isotope ratios by using data on heads. The nn' terms are due to the fact that the data are for heads.

Effect of Length of Day on Flowering and Grow

AN attempt has been made to confirm the worl Garner and Allard [1] done in America, under the c ditions prevailing in Britain at the Welsh Pl Breeding Station, and to test particularly the haviour of various strains of herbage plants un different lengths of day.

The plants, equal propagants, or pure line pla were grown in pots or boxes placed on trucks wh were run in and out of a three-sectioned hut so t they received 12, 9, and 6 hours' daylight. Con plants received the full natural daylight. Equal s water, and temperature conditions were provided far as possible.

The results obtained fall into three divisio namely:

I. EVER-BLOOMING TYPE.—Plants of *Poa Am* flowered normally under all light periods.

FIG. 1.—American Red Clover, photographed on July 29, showing, le right, control (many heads ripening), 12-hour plant (with small flow 9-hour plant (almost prostrate, with a few small heads), and 6-h plant (prostrate, in winter habit).

II. SHORT-DAY PLANTS—*Chrysanthemums* (v Mrs. William Buckingham): Subjected to treatm on May 9. Short-day plants, flower buds July open in early August. Controls, no buds August *Phaseolus vulgaris* (Runner Bean, Sutton's "Best All"): Treated plants were small and bushy, w thick nodes and swollen roots. Height of cont plants 50 in., height of 6-hour plants 9 in. Treat plants flowered 4 days earlier than control plants.

III. LONG-DAY PLANTS—(1) *Broad Red Clover* (Suffolk): Control plants started flowering May attained flowering zenith June 6; 12-hour pla started flowering June 28, attained flowering zen July 26; 9-hour plants started flowering July attained flowering zenith July 31; 6-hour pla have remained entirely in the winter habit. *Montgomery Variety*: Controls flowered freely fr July 16, reaching their flowering zenith about Ju 26. The 12-, 9-, and 6-hour plants were quite pr trate and in the winter habit on August 10.

ksfoot.—Some of the Cocksfoot results can be rmarised thus :

	First Panicle emerging.	Full Flowering (Pollen).	Ht. on 31/7.
rch Hay " strain :			
rol plants	19/5	5/6	34 in. ripe seed.
our plants	6/6	16/6	15 in. ripening.
ur plants	Remained in winter habit, good leafy growth, no signs of panicles at all, 6/8/24.		5 in.
ur plants			
ocks " type :			
rol plants	29/5	25/6	27 in. ripening.
our plants	30/6	29/7	9 in. full flowering just over.
ur plants	Plants as yet in winter habit, 6/8/24.		
ur plants			

liefly, the following have proved to be " long-day " ats :

asses.—Sweet Vernal, " Late " and " Early d Leaf " strains ; Meadow Foxtail, " Late ure " strain, " Early Hay " strain ; Cocksfoot

Fig.—Montgomery Red Clover, photographed on August 2, showing, ft to right, 9- and 12-hour plants quite prostrate in winter habit and ontrol plant flowering.

strains, " French Hay," " Danish Open," " Late Indigenous," and " Tussocks " ; Perennial Rye Grass, Early and late strains ; Timothy, Early strains. *Red Clover.*—Broad Red, American Medium, and Montgomery. *Oats.*—Grey Winter, Record, Orion, Ceirch duBach. *Radish.*—Scarlet Globe. *Foxglove.*

A more detailed account will appear shortly elsewhere. Thanks are due to Prof. R. G. Stapledon, who arranged for the necessary equipment and provided facilities for conducting the work, and to Mr. J. W. Watkins, Superintendent of the Welsh Plant Breeding Station Gardens, for careful attention to cultural detail. M. A. H. Tincker.

The Insect Fauna of an Indian Island.

It has been my good fortune to be associated with the late Dr. N. Annandale in the study of the fauna of a small island in the Chilka Lake, Orissa—the first work of its kind in India. This study has, I believe, a general interest, and I need scarcely apologise for presenting this brief analysis of the insect fauna of this island.

The physical features of Barkuda Island form the subject of a memoir by Annandale (1922), but it may be recapitulated here that the island is situated in the Chilka Lake on the east coast of India in lat. 19° 38′ N. long. 85° 12′ E., and lies in the extreme north-western corner of the Madras Presidency. In outline it forms a right-angled triangle, its longest side being about three-quarters of a mile long, and its shortest less than half as much : the total area equals about half a square mile. It is composed of stratified rocks covered in the interior with a thin layer of red soil, its geological nature, combined with a low average rainfall (as compared with that of the mainland), being responsible for the sclerophytic nature of its vegetation, a distinctive feature of which is the fig-jungles in which there is a dense undergrowth composed mainly of the shrub *Glycosmis pentaphylla*. The dominant tree in these ficetii is the Banyan (*Ficus bengalensis*), the decayed trunks of which are largely inhabited by termites. In inland areas where there is no ficetum, *Weihea ceylonica* is the dominant shrub, and the fig-trees are replaced by the Nim (*Barringtonia acutangula*) and *Craeteva religiosa*. The island is almost completely surrounded by a marginal zone of the trees of *Pongamia glabra*. Other common plants are the Euphorbias (*E. neriifolia* and *Opuntia* sp.), the Custard-apple (*Anona squamosa*), and the herbs *Crotolaria striata*, *Tephrosia purpurea*, and

Fig. 1.

Jatropha gossypifolia. Barkuda is separated from the mainland of the western shore of the lake by a channel only a mile broad, and is thus not out of the range of insect immigrants, even those of comparatively feeble flight.

Dr. Annandale's main object in studying the fauna of the island was that it provided an easy means of ascertaining the faunal and floral constituents of a limited area in the tropics, of a somewhat commonplace nature, and the results provide an interesting comparison with the biological features of other areas in the East. It was found that the species of insects inhabiting the island exhibited no morphological peculiarities in response to an unfavourable environment, but were for the most part common and widely distributed species able to exist on the island by reason of their physiological " hardness," or because they could adapt themselves to feed on strange and not very delectable food-plants. It would seem that a rich flora tends to produce a large and varied number of insect forms with a comparative scarcity of individuals, while the insect fauna of such areas as Barkuda are poor in species but rich in individuals.

In the accompanying diagram (Fig. 1), I have attempted to indicate (relatively) the approximate number of forms of the various orders (used in the old sense, *e.g.* Neuroptera to include Odonata, etc.) found on the island. It must be remembered that the totals include regular visitors and stray immigrants to the island. Geographically it seems to be part of the frontier between the faunas of the central and southern districts of the Indian peninsula. *Per exemplum* Barkuda appears to represent the extreme north-eastern limit in India of the dis-

tribution of the Pierid butterfly *Colotis calais amatus*. The South Indian element is strongly noticeable in its insect fauna. In the diagram, the total for "Hymenoptera" includes only the Aculeates; three-quarters of the neuropteroid insects are dragon-flies.

In the space at my disposal it is not possible to consider any special characteristics within the various orders. I may mention, however, that much taxonomic and bionomic information has been accumulated (especially with reference to the termites), and the reader is referred to the various reports on the fauna of the island. A considerable number of new forms have also been described, including such interesting insects as the hemipterous termitophile *Termitaphis annandalei* Silvestri. At some future date a complete summary may be provided.

CEDRIC DOVER.

London, July 25.

On the Spectrum of Ionised Potassium in Connexion with the Red and Blue Spectrum of Argon.

BY Zeeman and Dik (Proc. Amsterdam 25, 67, 1922), and Dik and Zeeman (Proc. Amsterdam 26, 500, 1923), it was found that in the electrodeless discharge (observations of McLennan, Dik and Zeeman) most of the lines of ionised potassium between 6594 Å and 3063 Å could be arranged in quadruplets.

If the frequency of the first line of each quadruplet is designated P, and the succeeding ones Q, R, S, it was found that

$$Q = P + 847$$
$$R = P + 1695$$
$$S = P + 2542.$$

For the red spectrum of argon, exhibited under the uncondensed discharge, and for λ below 4704 Å, Rydberg, in 1897, found a similar regularity. Paulson extended those results, and Meggers increased their accuracy. The frequency relations for the red argon spectrum are, with similar notations:

$$B = A + 846{\cdot}1$$
$$C = A + 1649{\cdot}3$$
$$D = A + 2256{\cdot}1$$

In both cases some of the "quadruplets" are incomplete. It is certainly remarkable that the number 847 occurs in both spectra.

We have extended the former investigation and have included an analysis of the "blue spectrum" of argon developed by the condensed discharge.

The following table contains the new results, together with those formerly given.

Argon, Red Spectrum (Rydberg).	Argon, Blue Spectrum.	Ionised Potassium.
A	p	P
$B = A + 846$	$q = p + 845$	$Q = P + 847$
$C = A + 1649{\cdot}3$	$r = p + 1695$	$R = P + 1695$
$D = A + 2256{\cdot}1$		$S = P + 2542$
	t	T
(411,57)	$u = t + 414$	$U = T + 413$

From this table it appears that the connexion between the spectra of ionised potassium and argon (blue) is closer than that between the spectra of ionised potassium and argon (red). We find the numbers 414, 845, 1695 characteristic for the blue spectrum of argon. The number 847 or thereab occurs with red argon, blue argon, and ion potassium; moreover, 1695 links blue argon ionised potassium.

Then there is the number 414, which occurs, as find, in numerous doublets of ionised potassium argon (blue). It may be mentioned that Rydb directed attention to the occurrence of the num 411·57 in the red spectrum of argon.

That there is a close numerical connexion betw the three spectra considered seems proved, but physical interpretation of the characteristic numb is quite unknown.

Tables and calculations will be published elsewh

Anomalous Adsorption.

BILTZ and Steiner (*Kolloid-Zeitschrift*, 1910, 7, 1 have described several cases of so-called "anoma adsorption," for example, the adsorption of N Blue and Victoria Blue B. by cotton and charc The adsorption isotherms rise to a maximum and off again with increasing concentration of the c stuff. Hatschek in his "Physics and Chemistry Colloids," 1922, p. 146, suggests that electrical fac may complicate adsorption "though these do very readily account for the maximum." Durin study of the dyeing of wool by Night Blue I h obtained adsorption curves of the same peaked fo using the same colorimetric method of estimation Biltz and Steiner. On examining the dyed w however, it could not be said that the colour was lighter in the case of the more concentrated soluti and some defect was therefore sought in the met of experiment.

It had been noticed that the dyestuff solut remaining after adsorption on the wool had a green blue colour when viewed by transmitted light in colorimeter, whereas the original Night Blue solut were a pure blue; this gave the clue to the def Although Night Blue solutions appear to contain free chlorine ions, the solutions remaining after sorption were both acid and contained chlorine i Hydrochloric acid is probably produced during sorption, and this has been shown to have a profo influence on the colour of Night Blue solutions. 2, 3, and 4 c.c. of a very dilute hydrochloric a solution were added to the same amounts of dyes solution and made up to the same volume with tilled water. These solutions were compared col metrically with a standard Night Blue solution of same concentration but containing no acid. If denote the concentration of the standard by un the *apparent* concentrations of the acid solution order were found to be 1·28, 1·50, 1·83, and 2 Furthermore, they showed the same greenish-b colour noticed previously. In the adsorption Night Blue by wool the amount of acid libera will increase with the amount of dye adsorbed, in consequence of this acid the apparent amoun dyestuff unabsorbed, estimated colorimetrically, be increased. Since the amount of dye adsorbe estimated by difference (original concentration kno the explanation of the peaked adsorption isothe is self-evident, and "anomalous adsorption," as scribed by Biltz and Steiner, has probably no existence. The determination of the true adsorpt curve is in progress.

Species and Chromosomes.[1]

By Prof. R. Ruggles Gates.

'is only since the beginning of the present century that the progress of biology has rendered possible ediscussion of this topic. When the "Origin of ecies" was written, chromosomes were unknown, ıd the study of nuclear division and the relation hromosomes to the life cycle only began in the enties and 'eighties of the last century. The names emming, Strasburger, Boveri, and many others are rected with the early work on chromosomes, when olic fixation and methods of sectioning first made ible their study. Flemming in 1882 first concluded 24 chromosomes was probably a constant number ne nuclear divisions of the cells of the Salamander. he following year van Beneden discovered, in ris, that the egg and sperm contained half as many mosomes as the somatic cells. From that time to the process of chromosome reduction has been ied with increasing intensity. Its general relation ne life cycle is now known in nearly all the larger ps of plants and animals.

ntil the end of the nineteenth century the study of structure developed quite independently of views rding heredity and evolution, although it had often en suggested that the chromosomes formed the basis heredity, and that they consisted of differentiated ions or elements. The rediscovery of Mendel's in 1900 was the beginning of a remarkable conver- e between two independent disciplines, the micro- oic study of cells and chromosomes on one hand, the observational and experimental study of edity and evolution on the other. There is no more king instance than this, of the convergence of two ependent lines of investigation, in the whole history biology.

t is equally significant that the advances in our wledge of chromosomes have been alternately based n studies of plants and animals, sometimes one and metimes the other being the basis of a particular new e of advance. Whichever has taken the first step in articular new line of departure, it has usually found firmation from the other. Even sex chromosomes, ich were first discovered in insects and were most ensively investigated in that group, are now known occur not only in mammals, including man, but also ertain Liverworts and in certain dicœcious flowering nts. Nothing so strikingly proclaims the unity of organic world as the profound similarity which has n shown to exist in the fundamental cellular pro- ses of the two kingdoms.

Moore had discovered synapsis, or the contracted se of the nuclei preceding the reduction divisions, Elasmobranch fishes, in 1896. It was believed that pairing of elements took place at this period of turation. In 1901 Montgomery suggested that napsis consisted in a conjugation of homologous nternal and paternal chromosomes before their paration in the reduction division. Guyer (1900), in tudy of spermatogenesis in pure and hybrid pigeons, d already pointed out that the separation of the pairs of chromosomes would account for cases of reversion in hybrids. In short, the chromosome mechanism was recognised as furnishing a basis for what we now call Mendelian behaviour at the same time that Mendel's laws were made known. A similar suggestion was made by Cannon (1903) in a brief study of the reduction divisions in hybrid peas.

Sutton in 1903 produced definite evidence of the pairing of homologous chromosomes of different sizes and shapes in the grasshopper Brachystola. In 1905 Strasburger showed the same arrangement of homologous chromosome pairs in plants, and in the same year Farmer and Moore suggested the term "meiosis" for the whole process of chromosome reduction.

For the original recognition of the individuality, or to use Wilson's term, the genetic continuity of chromosomes, we are largely indebted to Boveri, although the general acceptance of this view has resulted from an enormous amount of later detailed evidence. Among this evidence an important place is occupied by the work on hybrids, including that of Rosenberg (1904) on a species hybrid of Drosera, of Moenkhaus (1904) on hybrid fishes, and of Doncaster, Gray, Tennant, and others on generic hybrids of echinoderms, as well as the more recent experiments of Federley on species hybrids of the moth Pygæra. In all such cases the parental chromosomes maintain their characteristic differences of form and behaviour in the hybrid. These and a host of other results show that the chromosomes are not only self-perpetuating entities, through longitudinal division, but that they are also self-determining as regards their form, and we may now add as regards the finer elements of their structure.

In the last fifteen years particularly, the alliance between cytology and genetics in the experimental study of heredity and variation has become increasingly intimate. Beginning with the recognition of chromosome segregation in meiosis as the basis of Mendel's law of heredity, this was soon followed by the discovery (1906) of definite relations between chromosome numbers and mutations in Œnothera. Since 1910 Morgan and his colleagues have built up a combined system of genetical and cytological results in Drosophila which is unequalled in any other organism. Their theory of linkage and crossing-over has brought the phenomena of meiosis, chromosome structure, and heredity into still closer relationship. More recently Blakeslee and Belling have discovered chromosome relationships in Datura which parallel many of those formerly obtained with Œnothera, and in a striking series of experiments have extended those results in various directions.

In recent years, a number of predictions of peculiar cytological conditions have been made on the basis of genetic experiments, and afterwards confirmed by observation of the cells. An example is the work of Bridges with strains of Drosophila having an extra chromosome. This condition arises, as was first shown in Œnothera, through failure of one pair of chromosomes to enter separate nuclei in reduction, a process which is now known as non-disjunction.

The following may now be regarded as generally

[1] Opening paper of a joint discussion of Sections D (Zoology) and K (Botany) at the Toronto meeting of the British Association on August 12.

accepted facts concerning the chromosomes. They are bodies of relatively fixed size, shape, and point of attachment to the spindle fibres. Homologous pairs usually separate in meiosis and thus furnish the basis for simple Mendelian behaviour. Their number is generally fixed for each species so far as the germ-lineage is concerned. The relations of genetical crossing-over to chromatin behaviour are complicated and need not concern us here. Aberrant chromosome numbers arise in various ways and produce forms with different external characters. Such forms have been specially investigated in Œnothera, Drosophila, and Datura. The most striking changes found are tetraploidy ($4n$ chromosomes), triploidy ($3n$), and non-disjunction leading to forms with an extra chromosome ($2n+1$, $4n+1$, etc.). These conditions occur in all three genera, except that tetraploid forms have not been observed in Drosophila. The condition found in Œnothera particularly furnished the first experimental basis for a comparison of the chromosome numbers in various wild and cultivated species of plants.

When we examine the chromosomes of related species of plants and animals, differences in number or in size and shape of the chromosomes are often found. How have these differences originated? The answer to this question has already given us the beginnings of a chromosome phylogeny, which can now be soundly based on analogy with experimental results. The case of *Œnothera gigas* furnished the first experimental clue to the origin of tetraploidy. Many wild tetraploid species of plants are now known, and they must have arisen in some such way as *Œ. gigas* appeared, *i.e.* as mutations. The tetraploid and higher polyploid species are turning out to be surprisingly common in plant genera, though apparently much less frequent in animals.

Before considering further the phenomena of polyploidy, let us attempt to classify the various types of change which are indicated to have taken place in the phylogeny of chromosomes by the comparison of related species or genera. We may mention:

1. Polyploidy, or the development of higher multiples of chromosome numbers.

2. Transverse segmentation or fragmentation of all the chromosomes, or of particular pairs. A phenomenon of this nature seems to have occurred on a large scale in the phylogeny of the Liliaceæ, where in such genera as Yucca, Albuca, and Eucomis, a number of pairs of short chromosomes take the place of certain long pairs in other genera. In the tetraploid *Primula Kewensis*, a transverse segmentation of all the chromosomes is shown by measurements (Farmer and Digby) to have taken place. In certain species of Hyacinthus and Carex the sum of the lengths of a medium and a short chromosome is equal to the length of a long one, indicating that transverse segmentation of a long one may have taken place.

3. The end-to-end fusion of certain chromosomes. This is particularly clear, both from genetical and cytological evidence in certain species of Drosophila, and appears to have happened in various other cases. The basal number of chromosomes in the Muscidæ appears to be 6 pairs. In different species of Drosophila the n number may be 6, 5, or 4. In *D. melanogaster* and *D. Willistoni*, which have 4 pairs, two of these are long and broadly V-shaped, with a med constriction, and each of these has evidently b formed by the permanent end-to-end attachment two chromosomes. That *different* chromosome p have undergone this union in these two species shown by the different genetic relationships of t characters in breeding experiments; and that tendency towards end-to-end union still continues indicated by the recent discovery of a strain of *melanogaster* in which the two X-chromosomes in females have similarly become attached to each ot and behave as a single body.

4. The gradual diminution in the size of cert chromosomes until they disappear. That this evo tionary process has occurred in the Y-chromosome various insects, is indicated by its range of size different species, from as large or even larger t its mate the X-chromosome in some species, to a t body on the verge of extinction in others. Wil showed, for example, in the Hemipteran genus Nez that the Y-chromosome is nearly as large as the X *N. hilaris*, but very small in *N. viridula*.

In the Copepod genus Cyclops a gradual diminut in the number of chromosomes, from 22 in *C. stren* to 6 in *C. gracilis*, is accompanied by reduction in fifth pair of swimming feet. In another section the genus a parallel process has apparently occurr with corresponding gradual diminution of the chro somes from 14 to 10 and a small pair. Here phy genetic change has apparently been accompanied the continuous diminution in size of certain chro somes until they disappear. Whether such a proc should be looked upon as an orthophyletic cha arising in the germplasm is not at present clear, the subject is evidently worthy of further investigati

5. Irregular divisions or non-disjunction may l to forms with additional pairs of chromosomes. this condition becomes balanced it would be p petuated in a new species. This may have happe in various species.

6. The recent genetic evidence from Drosophila a the behaviour of the chromatin in such forms *Œnothera lata*, indicate that not only may chroma fragments enter a nucleus and afterwards divide, also that portions from one chromosome may beco attached to another and thus alter the genetic relati ships of the factors concerned. This process is which must also be considered as important in evolution of species.

7. In the genus Carex, Heilborn (1924) has sho that the haploid numbers in forty-four species from 9 almost continuously to 42 and 56, but with multiple numbers. With increase in numbers th is a general decrease in size of the chromosomes, a the same is true of certain other genera, such as Lactu This is regarded as due to a limitation in the capac of the cell for producing chromatin. Heilborn sugge that one of the most important methods of chro some increase in Carex has been by mutations of *Œnothera lata* type followed by a division of the ex chromosome.

8. Certain species and even genera with new chro some content have probably arisen through crossi There is some evidence, both cytological and morp logical, that cultivated maize may have arisen fro

cross between the Mexican Euchlæna and some species of grass belonging to the Andropogoneæ. A much rarer case is the one recently described by J. Clausen. He finds that *Viola tricolor* and *V. arvensis* have respectively 13 and 17 chromosomes as haploid numbers. In a cross the F_1 plants have 30 chromosomes, but in certain of the pollen mother cells 47 were found, *i.e.* 13+17+17, a condition of semi-tetraploidy. Two later generations of plants were grown from these hybrids, the chromosome number continuing 43-46. When the chromosome number is a very unbalanced one in a hybrid, as in crosses between diploid and tetraploid forms, irregularities of meiosis usually occur with loss of chromosomes until the diploid condition is reached in the later generations of offspring. In this Viola hybrid, with less disparity in numbers and a doubling in one parental set of chromosomes, the hybrid may later settle down to uniformity, in which case it might be regarded as a new species with higher chromosome number arising from crossing. Probably various species with increased chromosome numbers have been produced in this way, as Winge has suggested.

It is thus becoming clear that chromosome changes have arisen in a variety of ways, including transverse segmentation or fragmentation, end-to-end union of certain pairs, gradual diminution and disappearance of certain chromosomes, non-disjunction, rearrangement of portions of chromosomes, crossing of species having different numbers, and polyploidy. In some of these cases, of course, a certain amount of nuclear and cytoplasmic readjustment may be involved, but we have no present knowledge of how this takes place. In the simplest cases of tetraploidy all the external changes appear to follow directly from the doubling of the chromosomes.

All of these processes of chromosome change have had their place in the evolution of the germplasm, but certain of them appear to have been characteristic of particular genera or families. Our knowledge of polyploidy is at present much more extensive than any of these other processes, and it is on an experimental basis.

From the work of the last fifteen years, it has become clear that polyploidy has played an important part in the evolution of many plant genera and families, and that it is of particularly common occurrence among the varieties of cultivated plants. If tetraploidy can be brought about, as seems likely, by a lowering of temperature when the fertilised egg is beginning to divide, then one may perhaps understand its prevalence in plants and its relative infrequency in animals where temperatures are more controlled. But that it can be produced in other ways is shown by its experimental production in mosses by wounding (Marchals), in Solanum by grafting (Winkler), and semi-tetraploidy at least by crossing.

The cases of polyploidy in plants that have now been investigated are far too numerous to be discussed here, but reference may be made to a few of them. The genus Rubus, in which Longley (1924) has recently found $2n$, $3n$, $4n$, $5n$, $6n$, and $8n$ species, has 7 as basal number. The basal number of chromosomes in Rosa is also 7. In the genera Prunus and Potentilla the fundamental number is 8, and several species of Potentilla are known to be tetraploid. In Cratægus, where $n=16$, Longley (1924) has found $2n$, $3n$, and $4n$ species. If 16 is the fundamental number in this genus, then the genus must have originated in connexion with a tetraploid mutation. In some species of Alchemilla $2n=64$ and they are therefore octoploid in comparison with the fundamental number. It is evident that further chromosome studies in such families as the Rosaceæ will throw light on the origin and relationships of genera. The fact that such notoriously polymorphic genera as Rosa, Rubus, and Cratægus are all found to show polyploidy in a high degree is a discovery too fresh for its significance to be fully realised.

Similarly in the evolution of various other genera and families, higher and higher polyploid numbers have been reached. Thus in the genera Chrysanthemum, Rumex, and Rosa, species are found which are $2n$, $4n$, $6n$, and $8n$ in their chromosome constitution. Some of these genera also have $3n$, $5n$ and even $10n$ species. Many of these species are apogamous, and where the chromosome number is an unbalanced one as in $3n$ and $5n$ species, it can only be maintained by apogamous or vegetative reproduction. Thus these unbalanced species must always have been apogamous from their origin.

The conditions in the wheats, where $n=7$, may be briefly mentioned. Einkorn wheat (*Triticum monococcum*) is diploid, the species of hard wheat are tetraploid, and the Vulgare wheats (soft), which comprise our highest yielding modern sorts, are hexaploid. When members of different groups are intercrossed they produce sterile hybrids. All three groups go back to prehistoric times. The tetraploid wheats presumably arose, like *Œnothera gigas*, through a sudden doubling in the number of chromosomes. The most probable hypothesis of the origin of the $6n$ condition is that it came from a $3n$ hybrid between diploid and tetraploid species, one such hybrid having doubled its chromosomes, perhaps in the fertilised egg, and so restored its fertility. In certain cultivated varieties of mulberry, the $3n$ condition is maintained by apogamy, and the same is true of the wild species *Eupatorium glandulosum* and *Erigeron annuus*. Similar polyploid conditions are being found in many cultivated plants, including bananas, pineapples, oats, and dahlias, so that much more evidence concerning the precise manner of origin of these conditions ought to be obtainable.[2] Enough is already known to show that several different kinds of, for example, tetraploidy exist.

The development of sterility between species has undoubtedly played an important part in evolution. How this condition has come about is still a matter of speculation, but we are beginning to get some light on the subject. The old view that forms which produced fertile hybrids must belong to the same species has completely broken down, as has the converse conception that in plants, sterile pollen is a proof of hybridity. One of the most interesting features of tetraploidy is its relation to the development of sterility. As has been pointed out elsewhere,[3] if a tetraploid form such as *Œnothera gigas* arises in Nature, its hybrids

[2] Some of these subjects have been more fully discussed elsewhere Polyploidy, *Brit. Journ. Exptl. Biol.*, I, 153-182, 1924.
[3] NATURE, 1922, vol. 110, pp. 179, 447.

with its diploid parent must contain an unbalanced chromosome content, and this leads to the dropping out of chromosomes in later generations until the diploid number is restored.[4] The triploid form can only perpetuate itself by developing apogamy (as certain triploid species and varieties have done) or by doubling its chromosomes, thus producing a hexaploid form. In all three cases new centres of stability will be reached, which are starting points for fresh variations. The essential conditions for physiological isolation are produced, because the cross-breds will be unbalanced and unable to perpetuate themselves, while the original diploid and tetraploid forms will go on as independent lines of descent.

Blakeslee [5] and his collaborators have recently gone a step further and made the important discovery that the tetraploid mutation from Datura is almost completely sterile with its diploid parent. This is the first time that a form has been shown to appear in cultivation which is sterile with the form that produced it. In other respects it appears to be a complete parallel to the case of *Œnothera gigas*. It is thus proved not only that germinal changes can take place leading to new centres of variation, but also that they may be accompanied by practically complete sterility with the parent form. The origin of species which fail to cross with their parents, or of forms which produce sterile hybrids, is thus seen to be concerned in many cases with morphological changes in the chromosome content, such as tetraploidy.

In this way tetraploidy and the higher forms of polyploidy, as well as other types of chromosome change, have been of great importance in evolution, since they have the effect of physiological isolation even when there is no isolation in space. Genera and species which are tetraploid in comparison with related forms may be expected to have arisen in Nature in this way. Nor is this condition confined to higher plants, since various mosses and ferns, and Isœtes, are known to show similar conditions.

The study of chromosomes thus leads to results of far-reaching importance for evolution. It is of the highest importance for taxonomy in determining the relationships of species and genera. With advancing knowledge and quicker methods of examining chromosomes, the time should come when the description of a species is not considered complete until the morphology of its chromosome group is known, for visible chromosome differences, when they occur, throw important light on relationships. With further knowledge we shall doubtless learn much concerning the phylogenetic nature of the various kinds of chromosome change which have been outlined here. They suffice to indicate that there is a fundamental evolution of the germplasm, of which changes in specific characters are merely the external expression. Already as regards tetraploidy these changes have been experimentally analysed and we know something of the conditions which bring them about.

How the environment, acting on the organism, may have influenced other kinds of chromosome change we do not know at present. But it is well to remember that if a radium atom can undergo spontaneous change and break-down, then the infinitely more complex physical arrangement involved in a group of chromosomes may be reasonably expected to undergo equally spontaneous changes, especially during the complicated process of meiosis. It may also undergo alterations in which the environment of the cell has only been very slightly concerned. As an additional means of investigating phylogeny, the chromosomes have already furnished evidence of the highest importance, and their further study will no doubt throw important light upon the methods of evolution.

Modern genetics has led us to deal, as Bateson has said, with the world of gametes which form the background for the visible inherited variations of species. The next decade of comparative and experimental work with chromosomes will bring the realisation that in the secular changes of the chromosomes, however controlled or determined, we have a means of understanding how the cell unit, and through it the organism, has varied in structure in the past from species to species. This gives a new line of approach, of fundamental importance, in the analysis of the processes of evolution. It is to be hoped that its significance will be recognised not only by experimental evolutionists as an additional line of evidence in tracing phylogenies, but also by taxonomists as a necessary element in their discrimination of genera and species.

From a phylogenetic point of view, two important principles have emerged from the work of recent years in experimental evolution and other fields. One of these is the principle of parallel mutations, which introduces a new element of fundamental importance into the reconstruction of phylogenies. The original case of parallel mutations experimentally determined was that of the *lata* mutation from *Œnothera Lamarckiana* and from *Œ. biennis*, both mutants having 15 chromosomes and the same peculiarities of leaf and habit and sterile pollen, but each having the flower-size of the species from which it was derived. Innumerable cases of parallel variations are now known in plants, and many in animals. They appear to have originated as mutations. Vavilov, in particular, has directed attention to their frequency in cereals, Leguminosæ, and other families. When their significance is appreciated by systematists they will have a profound effect on present conceptions of relationships and phylogeny, for they show that many similar variations have occurred over and over again in unrelated groups.

The other principle to which I may make a brief reference has been emphasised particularly by palæontologists in recent years.[6] We may call it *orthophylesis* to avoid the special connotations of previous terms. It consists in the recognition of longer parallel phylogenetic trends in different lines of descent. What relation, if any, these orthophyletic trends bear to parallel mutations remains to be investigated. But it is possible that some of them, at any rate, as pointed out earlier in this paper, may be the result of changes initiated in the chromosomes. In any case the comparative study of chromosomes offers one of the most promising lines of advance in experimental evolution.

The Light emitted from Solidified Gases and its Relation to Cosmic Phenomena.

By Prof. L. VEGARD, University of Kristiania.

IN previous communications [1] I have given accounts of investigations on light emitted from solid nitrogen exposed to cathode rays and its bearing on the auroral spectrum. The conclusion was reached that in the auroral region the temperature was so low that nitrogen existed partly in the form of minute crystalline particles. If these particles are of molecular order of magnitude, the state is very much like a gas, from which, however, it differs in one respect. The constituent particles are not molecules with identical mass, but each particle may contain a more or less arbitrary number of atoms arranged in a space lattice characteristic of the solid state. This state, which is something between a gas and a solid, we shall call a pseudo-gaseous state.

Although it is difficult or perhaps impossible to produce this pseudo-gaseous state in laboratory experiments, still I was able to show that a layer of solid nitrogen when bombarded with cathode rays of small velocity gave a spectrum which was essentially the same as the auroral spectrum. In the green, the spectrum from solid nitrogen consisted of two bands, N_1 and N_2, corresponding to the auroral lines 5577 and 5230, and in addition it showed in the blue and violet the band-heads which are typical for the auroral spectrum.

The work has been continued at the Cryogenic Laboratory of Leyden and I have been able to study the new effect under varied conditions, with different kinds of rays, and I have also experimented on layers of various gases. In order to determine more exactly the position and structure of the bands, I have used a spectrograph of considerable dispersion. With the largest dispersion used, the distance between the yellow helium line (5875·6) and the green helium line (5015·7) was 27 mm.

I have obtained about a hundred spectrograms of the light effect from solidified gases and made a number of interesting observations which will be dealt with in greater detail in a later work. In this article I propose to give a short and preliminary account of some of my recent results.

Already in my first publication I mentioned that while the line N_2 was fairly sharp, N_1 was broad and covered the spectral region 5525-5660, and further it showed some structure. The spectrograms at larger dispersion [2] showed that N_1 had three maxima, one strong and two weak.

The position of the maxima varies somewhat with the experimental conditions. From one of my spectrograms with large dispersion I find that N_1 covers a region between 5528 and 5655. For the principal maximum I find $\lambda = 5555$, and for the two weak ones 5611 and 5649. Also with the greater dispersion, N_2 appeared as a single but somewhat diffuse line with a wave-length 5229·4, which agrees very well with the wave-length (5230) given in my first publications.

So long as we are unable to experiment on a pseudo-gaseous state of solid nitrogen, we cannot make an exact comparison between the wave-length of N_1 and that of the prominent green auroral line. Under the conditions of the experiments, N_1 does not define any definite wave-length, and we can merely state that N_1 is extending on both sides of the auroral line. The sharpness of the latter must be due to the smallness of the particles, and the prominent green auroral line is to be regarded as the limiting aspect of the band N_1, when emitted from solid nitrogen particles of molecular order of magnitude, which exist in free space.

I have been able to make some experiments which actually show that the bands get sharper when the particles are reduced in size. When an inert gas which contains traces of nitrogen is condensed on the cold surface, the layer will contain small nitrogen particles surrounded by an inert substance. In this state, we should expect nitrogen to behave in a similar way as if the particles existed in free space. Experiments were carried out in mixtures of argon and nitrogen. In one series I used canal rays, in another swift cathode rays; but in all cases I found that the N_1 band became narrower when the concentration of nitrogen became smaller.

At the same time I observed the remarkable fact that *the position of the principal maximum changes with the nitrogen concentration*. For small concentrations the principal maximum approaches a wave-length 5604. Thus with varying composition of the mixture the principal maximum oscillates between the values 5555 and 5604. The "secondary" maxima seem to disappear when the concentration of nitrogen is very small.

The motion of the principal maximum approximately follows the relation

$$\lambda_0 - \lambda_p = \frac{p}{100}(\lambda_0 - \lambda_{100}),$$

where λ_p is the wave-length corresponding to the percentage p of nitrogen and λ_0 and λ_{100} are the limiting positions.

The motion of the band may be due partly to the change of the average size of the nitrogen particles and partly to a mutual influence between argon and nitrogen. Perhaps an X-ray analysis of the crystalline mixture would give some information regarding this point. At any rate, the experiments indicate that a reduction of the size of the particles makes the band sharper, and that the position of the line corresponding to a pseudo-gaseous state need not coincide with any of the maxima observed in ordinary nitrogen under the conditions of my experiments.

The contraction of the bands does not seem to be essentially effected by change of temperature. By working under reduced pressure with liquid hydrogen, the temperature of the layer was lowered from 20° to 14° K.; but there was no contraction of N_1 to be observed, although a change of a few per cent. would have been detected.

The experiments in argon mixtures also give an interesting illustration of the extremely high emission power of solid nitrogen. Even very "pure" argon contained sufficient nitrogen to give a marked emission of N_1 and N_2, and the nitrogen afterglow. The addition

[1] Proc. Roy. Akad. Amsterdam, vol. xxvii. Nos. 1 and 2; NATURE, vol. 113, No. 2846, p. 716; C.R. Acad. Sc. t. 178, p. 1153.

[2] Spectra with larger dispersion were obtained about the middle of March.

of about 0·1 per cent. of nitrogen to the "pure" argon considerably increased the nitrogen effect.

As shown in my earlier communications, slowly moving cathode rays gave in the blue and violet just the same negative and positive band-heads as those typical for the auroral spectrum. The effect has since been photographed with a quartz spectrograph through a quartz window, and the spectrum in the ultraviolet showed the same positive band-heads as those observed in the auroræ.

When the layer is bombarded with a powerful beam of cathode rays from a Wehnelt cathode, a deep red luminosity appears near the layer, and the colour has the same appearance as a red colour very characteristic of the auroræ. A spectrum obtained on a panchromatic plate showed the same two red bands which I have obtained on auroral spectrograms. Thus from the system I am experimenting upon I get the characteristic bands and lines of the auroral spectrum from red to ultraviolet.

Now it is of great importance to see whether also positive rays might give the typical auroral spectrum. For this purpose a considerable number of experiments have been made with canal rays acting on nitrogen, hydrogen, and helium.

Exposed to canal rays, solid nitrogen emitted both N_1 and N_2; but in the blue, violet, and ultraviolet, the canal-ray spectrum was quite different from the typical auroral spectrum. In this spectral region the canal-ray spectrum was dominated by a series of diffuse bands, which extended far into the ultraviolet. Moreover, as has been shown before, the canal-ray spectrum has a number of strong lines not present in the auroral spectrum.

Thus neither in the solid nor in the gaseous state of nitrogen do the canal rays produce the nitrogen spectrum observed in the auroræ, and hence we conclude that by far the greater part of the auroræ must be caused by cathode rays.

Cathode rays which were produced by an induction coil and had a fairly large velocity corresponding to a spark-gap of 5-6 mm. between spheres 1 cm. diameter, gave a very brilliant effect, showing N_1 and N_2 very strongly. Under these conditions I also obtained the same series of diffuse bands as were obtained with canal rays, but their intensities were now relatively smaller.[3]

Nitrogen-argon mixtures were investigated both with canal rays and swift cathode rays, and some results with regard to the variations of N_1 have already been described. Not only N_1, but also the diffuse canal-ray bands in blue and violet, were seen to contract as the concentration of nitrogen became smaller, and at the same time each maximum moved towards shorter wave-lengths. When the layer of argon only contained small quantities of nitrogen, the bands were concentrated into fairly well-defined diffuse lines. In the blue and violet there were two bands, each of which was concentrated into one pair of lines, one pair at $\lambda=4523, 4473$, and the second at $\lambda=4236, 4211$.

These bands are no doubt one state of development of the two bands observed by Lord Rayleigh in the light from the night sky. This means that this light should be produced by fairly slow positive rays.

[3] It remains still to be shown that the bands in blue-ultraviolet are not produced by canal rays, either retrograde rays or rays produced by imperfect rectification of the current.

When the layer of solid nitrogen has been bombarded for some time with canal rays or swift cathode rays the afterglow becomes very persistent. Two or three minutes after the rays are cut off the light intensity from the layer may remain practically constant for hours or perhaps for days. Usually the afterglow only shows the band N_2; but when the persistent afterglow is very strong, I have also observed N_1 and the bands in the blue.

When the liquid hydrogen disappears and the temperature of the layer gradually increases, the stored energy is suddenly released under intense light emission showing N_2 very strongly, but also N_1 and the diffuse bands in the blue appear very strong. Thus N_1 and N and the series of diffuse bands in the blue-ultraviolet are emitted in the afterglow and consequently from the very interior of the solid substance.

When the temperature of the layer increases to a certain point the appearance of the solid nitrogen suddenly changes. At the temperature of liquid hydrogen the layer resembles a piece of ice and sticks to the cold surface; but at a certain point the layer assumes a powdery form, and if it is somewhat thick it falls down from the cold copper surface. The existence of two modifications of solid nitrogen was discovered some years ago by means of cooling curves,[4] and the transformation is found to take place at a temperature of 35·5° K.

Now the energy stored in the afterglow radiates out at the very moment that the layer passes over into the other modification. The phosphorescent energy cannot exist in the modification which is stable above 35·5° K. This phenomenon is explained from the fact that the light given out by the afterglow is characteristic of the modification of solid nitrogen which is stable below 35·5° K., for if nitrogen in the other modification is exposed to cathode or canal rays, N_1, N_2, and the diffuse bands in the blue-violet are not emitted. The luminosity, which is very faint, shows a different spectrum and no afterglow.

This fact has a very important bearing on cosmic phenomena. In that part of the atmosphere where N_1 and N_2 are emitted the temperature must be below 35·5° K., and the isothermal surface 35·5° K. marks the transition between an upper layer very easily excited to light emission and a lower layer which has lost this high emission power.

In this way I think we get the explanation of the fact found by Lindemann that the meteor frequency as a function of altitude shows two maxima with a very marked minimum in between, for below the isothermal surface (35·5°) the meteors may often seem to disappear because they produce very little light until farther down they become luminous on account of heating. Now the height of this isothermal surface ought to be greater in the day than in the night, greater at the equator than at the poles, and greater in the summer than in the winter. Indeed, Lindemann has found that the height of the upper frequency maximum, caused by nitrogen below 35·5° K., increases from 75 km. in the winter to 85 km. in the summer.

The relative intensity of the lines N_1 and N_2 is of importance not only from a physical point of view, but also in connexion with the auroral problem. The

[4] W. H. Keesom and H. Kamerlingh Onnes, Proc. Roy. Akad. Amsterdam, 24, p. 1315.

tisity ratio N_1/N_2 increases generally with velocity the density of the bombarding electric rays, and itrogen-argon mixtures it increases very much when e nitrogen concentration diminishes. With very nl concentrations N_1 predominates as compared with This effect indicates that N_1/N_2 increases as the itogen particles get smaller, and it may thus account rhe predominance of the auroral line 5577 in the ral spectrum.

he great variability of N_1/N_2 makes it difficult to ermine exactly the minimum cathode ray velocity essary for producing the two bands. Perhaps they ire the same velocity, only that the intensity of N_1 usually is very small at small velocities. At the rent time, I have been able to follow N_2 down to cities corresponding to 78 volts, and N_1 down to 6 volts.

non-luminous layer of solid nitrogen was not ile luminous by ultraviolet light from a condensed luminium spark. X-rays, however, produced the rnary afterglow.

When the layer is in the state showing the persistent frglow, conditions are different. In this case light from an ordinary incandescent lamp with a tungsten filament produced a very marked increase in the intensity of the afterglow. In some cases the intensity underwent very marked periodic variations with periods of 5-6 seconds, and I could count 8-9 periods.

Layers of solid oxygen, ammonia, and argon have been bombarded with both cathode rays and canal rays, and a layer of nitrous oxide with canal rays only. With the exception of argon, the light effect was feeble and gave no afterglow. The fairly strong effect observed from an argon layer was to a great extent due to traces of nitrogen, which produced a weak afterglow and a strong emission of N_1 and the canal-ray bands of nitrogen. The afterglow showed only the line N_2 and no other visible light in the spectrum. Thus argon itself gives no afterglow, and the real argon effect, although somewhat stronger, perhaps, than in the case of oxygen ammonia and nitrous oxide, is an effect of the same type as shown by these gases.

The experiments on layers of various substances thus show that the light effect from nitrogen at temperatures below 35·5°, which is applicable to the auroral spectrum, is a light effect of a unique and singular type.

The Beam System of Radio Telegraphy.

THE paper read by Senator Marconi to the Royal Society of Arts on July 2, and published in the Journal of the Society for July 25, describing the results he has obtained over very long distances by short wave directional radio telegraphy, is one of great importance and marks an epoch in the development of long distance radio communication. Mr. Marconi reminds us that more than twenty-eight years ago he showed Sir William Preece the transmission and reception of signals over a distance of nearly two miles by a "beam" system, using short waves and reflectors. Curiously enough, at that time he could only transmit signals by means of an antenna over a distance of half a mile. The rapid and spectacular progress made, however, by the long wave system in those early days diverted attention from short wave research, although the latter could be emitted in beams in definite directions.

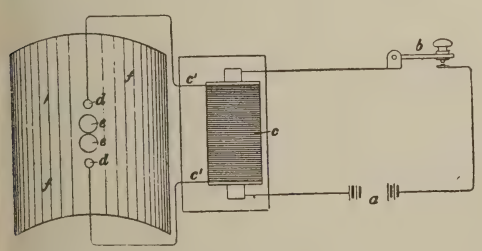

FIG. 1.—Spark transmitter and sheet metal reflector, 1896.

In 1899, Mr. Marconi read a paper to the Institution of Electrical Engineers in which he pointed out that a short wave system would be of value in connexion with lighthouses and lightships in foggy weather, enabling them to locate dangerous points. He also projected a beam of waves across the lecture room, a bell ringing only when the reflector faced the receiver (figs. 1 and 2).

In 1916, in conjunction with Mr. C. S. Franklin, he again began to make researches with directive beams. The reflectors used at first were not solid sheets of metal, but consisted of wires forming a cylindrical parabolic reflector, the antenna forming the focal line of the cylinder (Fig. 3). The reflectors now used consist of a grid of antennæ and a grid of reflecting wires arranged parallel to one another (Fig. 4). Special arrangements have to be made so as to ensure that the phase of the oscillations in all the wires is the same. The great value of reflectors was demonstrated by experiment, the energy received being increased about two hundredfold by their use.

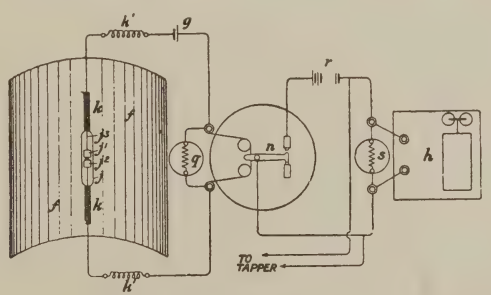

FIG. 2.—Coherer receiver and sheet metal reflector, 1896.

Many tests were carried out between the steam yacht *Elettra* and a small station erected at Poldhu which emitted waves about 100 metres in length, the frequency therefore being about 3,000,000. One definite result obtained was that the strength of the signals received during the hours of daylight varied inversely with the mean altitude of the sun over the space intervening between the two stations. It is wrong, therefore, to refer to distances covered during daylight as "day ranges." It shows also that the tests which were carried out partly within the tropics during the months of May and June were made under very unfavourable conditions.

The results prove quite definitely that the absorption factor given in the well-known Austin formula does not apply to short wave phenomena. It can be replaced by a factor which is approximately a linear function of the mean altitude of the sun calculated on the great circle of the earth which passes through the two stations. In regard to atmospheric disturbances and others, the origin of which is unknown, these appeared to be less troublesome during daylight than when working with a long wave system. During night time, even up to distances of more than 2000

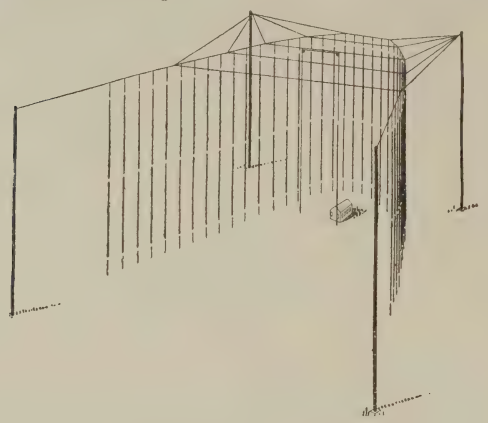

FIG. 3.—Parabolic vertical wire reflector, 1923.

miles, the signals received were so strong that extraneous disturbances caused no appreciable interference.

During the tests, the Poldhu transmitter consisted of eight glass valves in parallel, the input being only 12 kw. The radiated energy concentrated by the parabolic reflector in the direction of Cape Verde was about 9 kw. If no reflector had been used, about 120 kw. would have been necessary to get a beam in that direction of the same intensity. The receiving aerial was a vertical wire at a height of twenty metres above sea-level. The first series of tests was carried out without the transmitting reflector. Day signals were received up to Seville, which is 780 miles from Poldhu, although practically the whole of Spain, consisting of more than 300 miles of high and mountainous country, lay between the sending and the receiving station. At Gibraltar (820 miles), better signals were obtained, as the yacht was anchored in a more open space.

For greater distances the reflector wires were used at Poldhu. At Madeira (1250 miles) good signals were obtained, using 12 kw. at the sending station. At St. Vincent (2230 miles), Cape Verde Islands, it was still possible to get a few hours' daylight reception after sunrise and before sunset. The night signals continued to arrive with apparently unabated strength although the distance had been increased to about double what it was at Madeira.

The strength of the night signals at St. Vincent was estimated to be about 500 microvolts per metre of aerial wire, and no trouble was experienced from any kind of interference. It was calculated that night signals would continue to be received at St. Vinc even if the power at Poldhu were reduced to t tenth of a kilowatt.

After this voyage, the station at Poldhu was i proved, the power being increased to 20 kw. Sir February of this year further tests have been ma A special short wave receiver was installed on t s.s. *Cedric*, and reception tests were carried out wi Poldhu during a journey of the vessel to New Yo and back. No reflectors were used at either en The results obtained confirm the earlier experimen Daylight signals could be received up to a distance 1400 nautical miles.

During this test one surprising result was obtain Mr. E. T. Fisk, of Sydney, Australia, reported by ca that he could receive the Poldhu transmissions p fectly well every day at his house from 5 to 9 P (G.M.T.). He also received them between 6.30 a 8.30 A.M. He used an improvised receiver consisti of a 2-stage high frequency tuned plate and grid wi one rectification. Every word that was sent had be read, and Mr. Fisk stated that the signals were bet than any he had received from the high power stati at Carnarvon. Further experiments on communic ing with Sydney were made, and consistently go results were obtained.

The experimenters conclude that during the morni period the waves start from England to Australia a westerly direction. The waves cross the Atlan and Pacific Oceans, a distance of approximately 12,2 nautical miles. In the evening they travel in easterly direction over Europe and Asia. This is t shortest route, being only 9380 miles.

In Canada, at Montreal, reception was possible sixteen hours out of the twenty-four. A success wireless telephonic test was made with Sydney May 30, the speech being intelligible and easily hea It is noteworthy that this great distance was obtain without the use of a reflector at either end. The

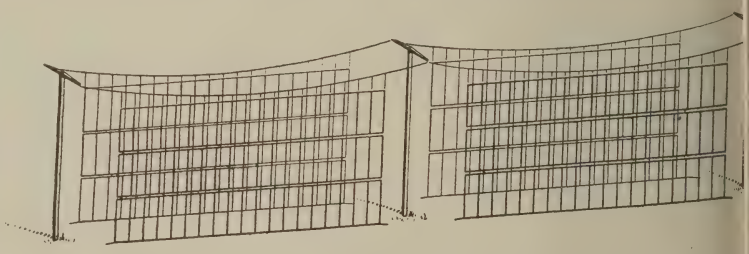

FIG. 4.—Vertical wire flat transmitting aerial and reflector, 1924.

of reflectors would doubtless be a great advanta in practice as it would both strengthen the receiv waves and cut out all the extraneous disturban except any which are proceeding in the line of t beam.

The aerials used were never worked to anythi approaching the limit of their carrying capacity. would be quite possible in practice to superimpo several waves and thus send several services sim taneously from the same aerial. The speed of worki obtainable by using short waves is very much hig than that obtainable by the long waves now in gene use.

Mr. Marconi calculates that the speed of signalling with a 100-metre wave, having a frequency of three million, will probably be a hundred times as great as that obtained with a frequency of 30,000, which is of the order of those that it is proposed to use for the Imperial Stations.

Further tests in June last were made between Poldhu and a small receiving station at Buenos Aires in the Argentine (5820 miles). A parabolic reflector was employed to concentrate the energy in a beam towards the Argentine. Although the power radiated was only 17 kw., strong signals were received for more than ten hours a day at Buenos Aires.

Mr. Marconi is strongly of opinion that by means of these small and inexpensive stations a far greater number of words could be transmitted between England, India, and distant British Dominions than would be possible by means of the previously planned powerful and expensive stations. The communications also would be much more secret than that obtainable by any of the present systems. In conclusion, he expresses his high appreciation of the excellent work done by Mr. C. S. Franklin in this connexion.

Obituary.

Sir George Beilby, F.R.S.

SIR GEORGE BEILBY died on July 31, in his seventy-fourth year, and when he had just laid aside the harness by which he had so long applied his talents with great effect in varied fields. His death caused widespread regret and directed attention to a notable record of public service in the linked relations of science, industries and citizenship. Fortunately for industry his early work brought him into close touch with the details of production as well as with scientific problems which confronted the chemical manufacturer. His skill and thoroughness in investigation, and his clear appreciation of the conditions of large scale work, enabled him to make successive additions of much value to the methods of industry. His relations with commercial production became such that he was in a position to follow up his researches in science by investigation of those of their applications which seemed to be promising. The success which from time to time attended his steady and enthusiastic labour enabled him to give to public purposes much of his energy, as well as to afford substantial support towards the advancement of science and the training of promising recruits for the ranks of scientific workers. Withal, the man and his life will remain in the minds and hearts of many, young and old, as a beacon no less bright than his work.

The son of Dr. G. T. Beilby, a well-known medical practitioner in Edinburgh, Sir George was born there in 1850. He was educated in Edinburgh schools and the University, and he joined the staff of the Oakbank Oil Company as a chemist in 1870. This appointment marked the opening of his professional work, which falls into three periods commencing in 1870, 1890, and 1914 respectively.

1870–1890.—A few years after joining the staff at Oakbank, Beilby became manager, and he held this position until about 1890; thus from 1870 to 1890 his work centred on the Scottish oil industry. He introduced improvements in several sections of the work, the most important being the use of large volumes of superheated steam which was passed into and through the spent shale in the retort, converting the carbon of the shale into water-gas and the nitrogen largely into ammonia. This procedure had several notable advantages, of which the main one was that it more than doubled the yield of ammonia—a result which saved the Scottish oil industry from extinction during the years of severe competition by petroleum.

The minor advantages of the process were: (1) the water gas, formed and heated in the lower part of the retort, conveyed heat internally to the shale in the upper portion, thus assisting to distil the shale at moderate heat; and (2) the removal of carbon from the spent-shale was practically complete, so that fires in the spent-shale "bings" which made these a nuisance in their neighbourhood were avoided. Beilby erected his original retort, operated on these lines, at Oakbank, but later he associated himself with the late Mr. James Young, who was experimenting on similar lines, and together they brought out the "Young and Beilby" retort (patented 1881), which is the prototype of the existing forms.

It is of interest to note that the use of steam in gas production with the purpose of recovering the nitrogen of the coal as ammonia was first proposed by Beilby, who practised it on an industrial scale at Oakbank Oilworks.

Towards the close of the first period of his work Beilby's attention had been attracted by the advent of the McArthur Forrest patents (1887) for the extraction of gold from its ore by means of cyanides. The probable demand for cyanides appeared to him to open an extensive field for chemical industry, and he proceeded to investigate the possibilities of preparing cyanide cheaply. This led shortly to his putting down a small factory near Edinburgh, where he produced the material in fair quantities at a price much lower than that reached by other makers.

1890–1914.—Beilby laid his cyanide process and its results before the directors of the Cassel Gold Extracting Co. of Glasgow (now the Cassel Cyanide Co., Glasgow). His process was accepted, and he became a director and partner in the firm. The process was used exclusively and profitably by this Company until 1900, when Castner introduced a new process for cyanide manufacture, on the development of which Beilby and Castner worked together. The improved process which they worked out was adopted by the Cassel Cyanide Company. At this time Beilby joined the board of directors of the Castner Kellner Alkali Co., Glasgow, and until the outbreak of war he took a leading part in the development of the two companies mentioned.

While this period consolidated Beilby's position as one of the pioneers and leaders of recent progress in chemical industries, it also brought to the front a parallel line of his activities in research—*the using of fuel*—and in this connexion it led to a steady increase

in the proportion of his time devoted to public work. Concurrently with his early work in the development of the recovery of ammonia from shale at relatively low temperatures, he had conducted experiments in steaming bituminous coal. From this onwards he never lost touch with the national problems of prevention of smoke and the economical use of coal. His work on fuel came prominently before the public when he took part in the inquiry of the Royal Commission on Coal Supplies in 1903. He then submitted an analysis of the purposes to which the British output of coal is applied and an estimate of the scope for economy attainable in each category of use by improved methods. His subsequent investigations were at first (1906–1912) directed to the production of a smokeless fuel for domestic purposes. The record of that work, communicated at the 1913 meeting of the British Association, showed that in treating comparatively non-caking coals satisfactory economic results could be obtained. The experiment was, however, discontinued, for the inquiries of the Royal Commission on Fuel and Engines for the Navy, 1912–13, gave a new and wider significance to low-temperature carbonisation. Lord Fisher was chairman of the Commission, and Beilby, as one of its members, could bring to the table not only full knowledge of ascertained fact, effective processes and attained results, but also a ready appreciation of the broad considerations specially relevant to the issues before the Commission. The Commission reported that the only means of rendering Great Britain to some extent self-supporting in the matter of fuel-oils lay in the development of a new carbonising industry founded on the distillation of coal at a temperature much below that used in gas-retorts or coke ovens.

1914–1923.—It was to the problem thus set to British science and British industry that Beilby gave of his best in the last ten years of his life. During the earlier War years his work and his thoughts were much diverted to other issues; but the fuel question was never far off.

When Lord Balfour, then First Lord of the Admiralty, formed the Board of Invention and Research with Lord Fisher as chairman, Beilby was naturally appointed to the Board. It is understood that in much of the great work with which that Board had to deal he proved most fertile in suggestion and wise in consultation and advice. On this section of his public service it may be recalled that in the King's birthday honours list for 1916 he was included among the new knights, being described as "a well-known chemist and inventor, who has specially studied fuel economy, and has rendered service to the Admiralty as a member of the Central Committee of the Board of Invention and Research, and in other ways."

In 1915, when it had been decided to reply in kind to the gas attacks first made by the enemy on the Ypres sector on April 22, 1915, Beilby was sent for by Lord Kitchener, at whose request he arranged that the Castner Kellner Company should provide a supply of liquid chlorine in cylinders. He became a member of the War Office Committee then formed to devise and test materials for offensive chemical warfare. On the formation of the Ministry of Munitions this matter was transferred to the new Ministry. Throughout these years Beilby gave his whole time to work for the Government, mainly in the Trench Warfare Department and its successor, in 1917, the Chemical Warfare Department. Needless to say, the work of the various advisory and supervisory War Research Committees was most strenuous and exacting. Beilby was indefatigable and resourceful always. He was much more. His calm, careful and sympathetic consideration of every intelligent suggestion or criticism were of great value in securing for the service the best use of the talents of the willing and able workers in the field. His individual contributions to scientific investigation of problems arising on appliances for attack or defence were always clear and definite. His guidance on points affecting design with the view of mass production or on suggestions for expediting manufacture was thoroughly practical. The anxieties of the time were many and often sudden. On such occasions Beilby was a great asset. His quiet manner, his refusal to be fussed, the personal sacrifices he made as a matter of course, and his consideration for all who worked with or under him, were of the highest value in the improvised organisations of the time.

But already in 1915 the Government had taken a first step to prepare for attacking the problems which would have to be faced on the advent of peace. A Committee of Council for Scientific and Industrial Research had been constituted, and in 1916 the Department of Scientific and Industrial Research was established, with a strong advisory council of men of science as the central feature in its organisation. Of this council Sir George Beilby was one of the original members. In its first year the council, recognising that fuel was at the root of British industry, advised that the Department should tackle the fuel problem. A year later, despite his other national work, Beilby was prevailed upon to accept the invitation to direct fuel research for the Department, put to him first by Lord Crewe, when Lord President of Council, and again by Lord Curzon when he succeeded to that office. The Fuel Research Board was set up in 1917 with Beilby as its chairman and as Director of Fuel Research.

The burden which Beilby thus took up was a heavy one, and at the initiation of the work he was closely engaged in the war activities indicated above. Moreover, the past strain had pressed him not a little and he had had to undergo an operation for appendicitis. While still feeling the effects of that, he had returned to his war work with his customary energy; indeed his spirit appeared to have carried him through without lasting effects.

The design, construction and equipment of the final Fuel Research Station at East Greenwich were carried through under Beilby's personal supervision, so that the station, its possibilities, its organisation and its staff represent his conception of what is required as the centre of national investigation and research as to fuel production and the using of fuel. The development of the relation of the Fuel Research Board and of its central station to investigations carried out in coalfields and other laboratories had necessarily to wait for more normal conditions, but this, too, had been arranged and initiated before he regarded the organisation as being on a basis so secure that he was justified in demitting the office of Director of Fuel Research.

By the end of 1917, the first year of the work of th Station, the problem set by the Fisher Commission o 1913 had been solved in its scientific and technical a pects sufficiently to permit home production of fuel- c under war-conditions if need had continued to p ss. Commercially it still stands a problem. The n rmal work of the Fuel Research Board has been n ted from time to time in these columns. It therefore s fices here to say that the whole organisation is to all i ents and purposes Sir George Beilby's creation. That e rly result of reference to the Board—the establish- r nt of the method of charging for town gas by the "therm"—is now recognised as one of those little things w ich exercise prevailing influence to the advantage of p oducers and consumers alike.

Sir George Beilby was never without a side interest (a hobby with a scientific bearing. He took a keen interest in colour photography and in microscopy. In the former he made himself expert in the use of the Lumière process in photographing mountain scenery in Switzerland and the Tyrol, and he applied it also in photomicrography. Indeed, some of his photomicrographs, prepared in 1913, were reproduced in a colour-plate published in NATURE of February 19, 1914. Microscopy, from being a hobby, became, and continued, for him a serious study. It was the only method of investigation which he could follow with satisfaction intermittently in casual short intervals in the busy daily life of a busy man. Faced, as a cyanide manufacturer, with the difficulty of finding any metal alloy which would withstand the action of ammonia at 350° C. for any length of time, he turned to the microscope for suggestions as to the conditions of the problem.

From this Beilby was led to investigate the effects of various forms of mechanical work on the crystalline structure of metals, for example, the disturbances which occur in the processes of polishing and burnishing. As usual he spared no pains in making himself a master of the technique of the methods which he employed to study his subject from every angle. He made an experimental study of a number of solids in various states of aggregation. His researches in this field, which were ingeniously planned and most accurately carried out, were of an entirely novel kind. He gave an account of this work in the May lecture which he delivered to the Institute of Metals in 1911. In his book, "The Aggregation and Flow of Solids," 1921, he published collected statements of his work on this subject, including his more recent investigations. The facts he recorded are those which he established by most careful work and observation repeated time and again. These and the theory of the hard and soft states of metals which he put forward in 1911 had a profound influence for several years on the development of metallography, and gave rise to a variety of researches designed to test the range of application of his theory. In view of recent researches on the constitution of matter it is difficult to judge the precise form of the theory which will ultimately be accepted, but there can be no two opinions as to the magnitude of the service he rendered to the elucidation of the changes produced in metal crystals by mechanical work of all kinds.

As a citizen—indeed in all relations—Beilby systematically shunned publicity. Even in matters of public interest for which he did active work, his help was so unobtrusive that it was little known unless circumstances made his emergence unavoidable. Education, training for and in research, smoke prevention, each succeeded in identifying him, but these were by no means the limits of his active help in affairs. In 1877 Sir George married Emma, daughter of the Rev. S. Newnham, and Lady Beilby has been a devoted coadjutor in many of his public interests. With her he was early among those who worked for the admission of women to professions, and this cause appealed to him in the first instance in the critical case of medicine. Their interest in students, particularly students of science, began many years ago, and only few have even a general idea of the extent to which he coupled financial help with advice as to courses of training or subsequent experience. Sir George was one of the trustees of the Carnegie Trust for the Universities of Scotland, and he took a keen interest in the details of the work of that Trust. He was a fellow of the Royal Society, and one of the first members of the executive of the National Physical Laboratory formed by the Society in 1900 with Lord Rayleigh as chairman.

It was, however, the Glasgow and West of Scotland Technical College—now the Royal Technical College—which indented most fully on his ready help in council. He was co-opted as a governor of the college in 1900, and on the Board of Governors his wide knowledge of men of science and of industry soon commanded the confidence of his fellow-governors, and his foresight did much to secure that the building then being planned was conceived on an adequate scale. In 1903 he became convener of the sectional committee on the departments of chemistry, technical chemistry and metallurgy. The scheme of teaching and the nature of the laboratory courses and appliances adopted were novel at the time, but have since proved applicable in other places. In 1907, on the death of Sir William Copland just when he had completed the task of raising funds for the erection of the new buildings for the college, Sir George Beilby was elected chairman of the governing body.

The new buildings and equipment secure, the governors and staff strove strenuously, and with success, to raise the standard reached in the college teaching and to develop the training of promising students in methods of research bearing on industries. In 1913 the college was affiliated with the University of Glasgow and was included among the institutions recognised for grants by the University Grants Committee. The raising of the college ideals and the effective efforts towards improvement of practice were largely due to the all-prevailing influence and wise initiative of the chairman. His fine personality was a great asset in every development of the college and its work.

One example of this may now be mentioned. Sir George had been providing funds year after year to enable good men to remain at college for training in research methods for a year or more after completing their ordinary courses. When the results of this encouragement had become amply apparent he set about placing this help and cognate facilities on a

permanent footing. A "New Development Fund" was established and started by an anonymous contribution of 10,000*l*. Sir George was the donor. He was one of those who knew how to use money to good purpose. The fund was well opened, and although the war years checked its growth it now amounts to 65,000*l*.

Sir George Beilby's fine personality was a great asset in every development of the Royal Technical College and of its work. His touch with students was, however, of long standing and it was real, informal and elevating. His house in Glasgow was for years a place of resort for young men. Music had a home there—Sir George himself was an artist in music; he was also a first-class craftsman; he built his own organ, buying only the pipes, and much of the refinement of its mechanism was of his own invention. Conversation there on current topics never flagged in interest although it often strayed. Personal talk or counsel on individual aims or on difficulties over study always refreshed the visitor.

In our world of to-day—its science, its industries and its humanities—Sir George Beilby has been a notable exemplar of the "veray parfit gentil knight."

We regret to announce the following deaths:

Sir William Bayliss, F.R.S., professor of general physiology in University College, London, on August 27, aged sixty-four.

Dr. John J. Stevenson, professor emeritus of geology at New York University and president in 1899 of the Geological Society of America, on August 10, aged eighty-two.

Current Topics and Events.

The recent conference at Oxford on "The Scientific Approach to Religion" was a notable event and aroused a good deal of interest in the Press and the public. The change of tone is amazing since the famous Diocesan Conference at Oxford in 1864, when Disraeli strolled in and declared himself on the side of the angels and not of Darwin. Of course the battle had been won long before this, but it was well that Oxford should be the scene of so striking a reconciliation after the half-century. The notes struck were, the abandonment of final and exclusive dogmas either on the side of science or of religion, and the possibility of a man of science being a theist and Christian, and of the "religious" person accepting all or any of the established conclusions of science. We imagine that nowadays few people will be found to dispute any of these propositions. We all agree in general terms; the difficulties arise when we come to define them. This could be illustrated from almost any of the papers read. For example, Dr. Rollin stated that the point of the theists had been demonstrated that the world in its essence was a form of energy, and energy, so far as all our knowledge went, did not come from nowhere. But would such a doctrine satisfy any theist who thought out carefully what he meant, or would it have convinced Ostwald that he was a theist? The fact is that such an eirenicon as was proclaimed last week in Oxford is rather testimony of general goodwill, of a change of temper, and of a readiness to examine, than of definite agreement as to really disputable points. For what it was, we heartily welcome it and would not add a word to hinder so healthy a process. We need above all to strengthen the bases of our intellectual and social amity, but let us make sure of the strength of the stones we lay. It would be a disaster if they crumbled into sand when we began to raise the superstructure.

At a recent meeting of the Wiltshire Archæological Society a discussion took place with reference to permission having been granted to a modern sect styling themselves "Druids" or "Church of the Universal Bond," who contemplate burying the ashes of their dead within the precincts of Stonehenge. The discussion was followed by a strong protest against this unseemly intrusion. It is only a few years since this well-known monument was handed over to the nation by a generous donor, and as it came thereby under the protection of H.M. Office of Works, it was hoped that this would effectually stop desecration and any future trouble. A question in the House of Commons regarding a rumour of the proposed burial of ashes, put by the member for the Salisbury Division to the First Commissioner of Works, elicited the reply that permission had actually been given. Apparently the Commissioner had been approached by the sect privately and gave the desired permission on his own initiative without consulting the Advisory Board or taking thought what the result might be. This deplorable attempt at vandalism is strongly resented in the County and by the public generally, who hold in reverence the mighty monument set up by our progenitors. The members of the "Church of the Universal Bond" have camped for a fortnight annually upon the downland about half a mile from Stonehenge, and the Office of Works, despite suffering irritation from them, generously gave permission for services to be held within Stonehenge. Instead of being grateful for this boon an insulting letter was sent in reply, asserting that the place belonged to the sect, and no advantage was taken of the concession. Apparently an attempt is now being made to secure a hold upon the place, and this move should be resisted vigorously and to the utmost by every one who has a regard for Stonehenge. It is ridiculous to think of a small and obscure set of people having the impertinence to arrogate a claim to this National Monument. With just as much reason another sect might arise calling themselves "Romans" and laying claim to Roman villas.

Spain is a country rich in archæological remains, and many are the investigators who have made notable discoveries there. English readers have been hearing from time to time about the work of Mrs. Wishaw and the founding of the Anglo-Spanish School of Archæology at Niebla, Huelva, in Andalusia. A long article on her discoveries appeared in the *Times* of August 23, and we have received the following note upon it from a contributor, M. C. B.:—Mrs. Wishaw's

vestigations cover a rich and interesting field of Roman remains, including waterworks, etc., which is not dealt with in the article. Next, many finds have been made dating back to pre-Roman (Iberian) times. These discoveries include objects of pottery, etc., many of them exceedingly important. It is perhaps a pity that Mrs. Wishaw has not concentrated on these two fields where such valuable finds can be made, and where she has already done work of undoubted service to the archæologist. Her chief interest and object, however, seems to be to demonstrate that Upper Palæolithic man flourished at Niebla, even arriving at the stage of building walls and making pottery, and the recent article is largely devoted to this subject. Although the writer has not yet had occasion to visit the Niebla site itself, he has had the opportunity of seeing some examples of the stone industries, and he can only unhesitatingly suggest that, unless there is something further to show, nothing is as yet advanced which in the least proves the occurrence of Palæolithic man there. The specimens seen were, in his opinion, at earliest no older than the Neolithic Age. It is to be hoped that Mrs. Wishaw will continue her work, more especially of the later cultures. Spain possesses the advantage of having in the person of Dr. Obermaier, of the University of Madrid, one of the most brilliant of European prehistorians, and he would undoubtedly be willing to help at any time in dating the finds.

On August 25 a report, unsupported by details, appeared in various newspapers to the effect that 4 inches of rain had fallen in six hours at Cannington, Somerset, during a "cloudburst." It has since been ascertained that 9·04 inches were measured at Crymore, one mile west of Cannington, at 9 A.M. on August 19. The observer estimated that, of this amount, 8·5 inches of rain and hail fell between 1 A.M. and 7·30 A.M. on this date. At the Bridgwater Water Works, Ashford, about one mile from the Cannington gauge, 4·50 inches were measured. Further particulars with regard to this downpour will be awaited with interest, and some suspension of judgment is necessary until the measurement has been finally confirmed. A fall of eight and a half inches at an average rate approaching two inches an hour is quite unprecedented in the British Isles, though this rate has of course been frequently exceeded in short periods. The total amount of 9·04 inches has only been exceeded on one previous occasion, namely at Bruton, Somerset, on June 28, 1917, when 9·56 inches fell. During the climax of that disturbance the rate of fall reached one inch per hour for two hours. A similar rate was observed in the great East Anglian rain of August 25-26, 1912. On the day of the recent "cloudburst," a depression was stationary over the northern part of the North Sea and shallow secondary disturbances were passing over the British Isles. The conditions were favourable for heavy local showers of a thundery character. No large amounts of rain were, however, measured at health resorts or Meteorological Office telegraphic reporting stations in south-west England. At Weston-super-Mare, the nearest station the observations of which are telegraphed to the Meteorological Office, the total fall for the twenty-four hours ending at 9 A.M. on August 19 was only 7 mm. (0·28 inch).

The Royal Society of Western Australia, as part of the commemoration of the Kelvin centenary, has instituted the award of a gold medal for research. The medal will ordinarily be awarded every four years, and the first recipient is Dr. William J. Hancock. This is awarded in recognition of the part which Dr. Hancock has played in the development of radiography and radiotherapy in Australia since the discovery of X-rays. Until recently Dr. Hancock was the Government Electrical Engineer and is an honorary member of the Institution of Engineers of Australia. Those who took up the practice of X-rays soon after their discovery had many difficulties to overcome, and for a long time their pioneer work entailed real scientific investigation, the results of which rarely found their way into print. Nevertheless, it was largely due to these men who began to apply X-rays for medical purposes that the technique has evolved on the present lines. Unfortunately, few of these pioneers escaped injury from the rays they were using, and we regret to learn that Dr. Hancock is not an exception in this respect.

In the Faraday lecture of the Chemical Society, which has appeared in the July issue of the Society's journal, Prof. R. A. Millikan devoted attention to certain aspects of atomic structure which are receiving particular attention at the present time, especially from the spectroscopists. As a preliminary he insisted upon the very definite nature of the proof we now possess of the existence of the electron, citing in this connexion his own famous experiments with the oil drop, which the latest researches in his laboratory have rounded off in a very convincing manner. Then, after summarising our knowledge of the nucleus atom, and emphasising the success of the orbit theory as worked out by Bohr and his followers, in particular Sommerfeld, he proceeded to describe briefly some recent experiments carried out by himself in collaboration with Mr. I. S. Bowen. Working with the so-called hot spark, in extreme vacua, these investigators have succeeded in obtaining spectra emitted by atoms which have, in extreme cases, lost as many as six of their "outer" electrons. In the first group of the periodic table they find evidence for the existence of "stripped" atoms, *i.e.* atoms which have lost all their outer electrons, of all the elements from lithium to nitrogen, the last-named having, of course, lost five electrons: in the second group they have obtained stripped atoms of all the elements from sodium to sulphur, which involves a loss of six electrons in the last-named. This constitutes a notable extension of the work of Prof. A. Fowler and of Prof. Paschen, who have obtained respectively the spectra of doubly and trebly ionised silicon, and of doubly ionised aluminium. For the identification of the lines, Prof. Millikan has derived much support from the increase of doublet separation with nuclear charge, which agrees well with the Sommerfeld relativity formula applied to his assumptions. Further consideration of his results has led

Prof. Millikan to conclude that the electrons possess inverse-square-law fields of force at orbital distances. The detailed account of this work has not yet been published, and will be awaited with keen interest by all physicists. It may be noted that Prof. Millikan comments unfavourably on the static atom, which he calls the "loafer electron theory," to express in brief the conception of "electrons sitting around on dry goods boxes at every corner, ready to shake hands with, or hold on to, similar loafer electrons in other atoms." He also objects to the term "proton," preferring "positive electron."

PROF. FREDERICK SODDY, professor of chemistry in the University of Oxford, has been elected a foreign member of the Reale Accademia Nazionale dei Lincei of Rome.

PROF. A. S. EDDINGTON, Plumian professor of astronomy and experimental philosophy in the University of Cambridge, has been elected an honorary member of the American Astronomical Society.

IT is stated in the *Times* that a French pilot, Lieutenant Thoret, has made a record gliding flight at the aerodrome of Les Alpilles, near St. Rémy-en-Provence. He remained in the air with the engine of his machine stopped for 9 hr. 8 min. The previous record was held by a German airman, who was in the air for 8 hr. 42 min.

FOR the past year, Dr. J. J. Simpson, Keeper of Zoology in the National Museum of Wales, Cardiff, has given a weekly chat on some natural history subject from the British Broadcasting Company's studio in Cardiff. He has dealt in one series with British mammals, and these are to be published shortly in book form by the Sheldon Press. He has now started a new series on "Romances of Natural History," and has already dealt with "The Eel," "Aquaria," "Sticklebacks," "The Honey Bee," "The Tadpole," "Our British Reptiles and Amphibians, etc.," and will, during the next few weeks, talk on "The Mayfly," "The Sponge," "The Salmon," "The Lamprey," etc. It is noteworthy that the Cardiff station was the first to inaugurate a series of such talks, and from the correspondence received it is evident that they are stimulating a wide interest in natural history. It was inevitable that such would be the case, because the various subjects are dealt with in non-technical language, and must appeal to a large public both juvenile and adult.

MR. F. EDWARDS, 83 High Street, Marylebone, W.1, has just circulated Catalogue No. 461 (British Empire Series, No. 4), containing particulars of nearly 800 books, engravings, and drawings relating to Africa. Copies are obtainable from the publisher upon request.

THE autumn announcement list of Messrs. Edward Arnold and Co. contains two memoirs which should appeal to readers of NATURE, namely, "The Life of John William Strutt, Third Baron Rayleigh, O.M.," by his son, the present Lord Rayleigh, and "Huia Onslow," by his widow, Muriel Onslow. Lord Rayleigh over a long period was a frequent contributor to NATURE, and a short series of articles on "The Iridescent Colours of Insects" by Mr. Onslow appeared in our columns not long before his death.

AMONG the autumn announcements of Messrs. Longmans and Co. is a book by Prof. S. J. Hickson entitled "An Introduction to the Study of Recent Corals," in which attention will be given to the structure by which corals capture and digest their food, the colours they display in life, and the means by which they propagate their kind. A descriptive of the structure of the soft parts of the coral and of its appearance when alive will be given wherever possible in the description of the genera.

ERRATUM.—In issue of August 30, p. 302, col. line 32, for "as well as the study of science, that letters" read "the study of science, as well as that of letters."

Our Astronomical Column.

ENCKE'S COMET.—This comet was of magnitude 14 at the end of July, but it has been rapidly approaching both sun and earth, and should now be visible with ordinary telescopes, especially before September 10, as the moon will be troublesome after that date. The following ephemeris, for Greenwich midnight, is from the B.A.A. Handbook:

	R.A.	N. Decl.	log r.	log Δ.
Sept. 5.	5h. 53·0m.	36° 46′	0·0845	9·9948
9.	6 21·4	37 10	0·0621	9·9670
13.	6 53·2	37 7	0·0378	9·9406
17.	7 28·2	36 28	0·0113	9·9170

The comet is nearest to the earth on September 30, and to the sun on October 31. It is due south about 7 A.M., but from its high northern declination it is observable in the east shortly after midnight. On September 5 it is near θ Aurigæ, on September 17 some 4° north of Castor. It should be followed until about October 20, after which it is inconveniently near the sun, and rapidly moving south.

ABSORPTION IN THE ATMOSPHERE.—M. J. Baillaud describes, in the *Comptes rendus* of the Paris Academy of Sciences, May 26, observations on the coefficients of transmission of light of different wave-lengths by the atmosphere, made at the Pic du Midi Observatory. A curve resulted, more or less parallel to that obtained by Rosenberg at Göttingen, but with somewhat higher values, and agreeing still better with that of Abbott and Fowle taken at Mount Wilson. On October 21, 1921, however, the values for small wave-lengths, about 380 mμ, were abnormally small, the curve running into the normal curve for longer wave-lengths. It was noticed that, although the sky was very clear, hoar frost was deposited on the outside wall of the observatory, and it is suggested that there may be a special absorption band for water vapour which has not as yet been observed in the laboratory when it is in the unstable state which precedes condensation. In support of this hypothesis, the observation of Nichols and Pacini, that the short wave-lengths are weaker in proportion to the long ones in light from clouds than in that from the clear sky, is brought forward. It does not seem possible that the abnormal absorption was due to ozone, as the amount of this gas required to produce the effect would be some seventeen times larger than that normally existing in the atmosphere.

Research Items.

THE DISTRIBUTION OF CALAMITIES.—Four months ago attention was directed in these columns (vol. 113, p. 653) to a proposal to study the distribution of calamities such as earthquakes, epidemics, floods, etc., under the auspices of the International Red Cross Committee and of the League of Red Cross Societies. A chief feature of this proposal was the issue of a quarterly review, *Matériaux pour l'étude des calamités*, to be edited by M. Raoul Montandon. We have now received the first number of this journal containing articles by the editor on the geography of calamities, and by M. Louis de Launay on earthquakes and volcanoes, as well as notices of memoirs bearing on the subject. The main object of the movement is the relief of suffering among populations affected by great calamities, and the editor urges that a useful preliminary step in the organisation of relief would be the publication of an atlas of the world showing clearly the site and extent of all catastrophes.

ACTIVE PHILIPPINE VOLCANOES.—The Bulletin for April 1922, recently published, in 1924, with the authority of the Government of the Philippine Islands, contains an article on the above prepared under the direction of Rev. José Algué, S.J., Director of the Weather Bureau of the Manila Central Observatory. Data relative to the Philippine volcanoes were previously published in 1901 and 1903. Since then volcanic events have been described in the Bulletins of the Weather Bureau, and observations of particular volcanoes were undertaken chiefly by the geologists of the Bureau of Science. The author mentions that the Apo and Sarangani extinct volcanic chain is in line with the Sanguire group, which is still active, being about 200 kilometres south of Sarangani, across the north-east part of Celebes Sea. A prominent peak or cone of the Apo group is Matutum; this is a very old volcano, its local name Matutum meaning "has burnt" or "fire out." With reference to the group Makaturing and Ragang, the author is inclined to believe that all the historic eruptions attributed to the former occurred in the latter. Dealing with volcanoes on Luzon Island, especial reference is made to Taal volcano, said to be probably the lowest in the world. It rises in the centre of Lake Bombon, at 14° 2′ N., 120° 57′ E.; the altitude of the lake is less than a metre above sea-level, and the highest wall of the crater is about 300 metres. The last eruption occurred in 1911 and annihilated everything around within a radius of several kilometres, causing about 1300 deaths.

CURRENT METER RATING.—The rating of a current meter for recording the discharge of streams is, of course, an important procedure, and every care is essential in order that the rating shall be carried out under conditions approximating as closely as possible to those obtaining in the actual observations. The customary method of calibrating a meter is to draw it through still water at known speeds, simultaneously observing the corresponding speeds of the rotor. The objection has been raised that this is merely a record of parallel and uniform stream line flow, taking no account of variations in the speed and direction of the filaments of water characteristic of ordinary river discharge. Such variations are generally grouped under the designation of turbulence. In NATURE of June 14, p. 872, we referred to a turbulence gauge designed by Mr. B. H. Wade of the Egyptian Ministry of Public Works to record the effects of turbulence in connexion with the computation of discharge in the river Nile. We have now received a copy of Physical Department Paper, No. 14, issued by the same service, in which Dr. P. Phillips discusses certain experiments which he has made on the rating of current meters by means of a new rating apparatus, brought into use at Abbassiya Water Works, by which the three essential observations (time, revolution of rotor, travel of carriage) are recorded automatically, so eliminating personal errors. This apparatus has been found to give results agreeing closely with the makers' average rating curve, and with the rating of the United States Bureau of Standards. It records a smaller number of revolutions per minute for the same velocity than does the old apparatus at Giza, the difference ranging between 2 and 5½ per cent. for different velocities. The new apparatus is explained with the aid of diagrams and photographs.

IMPLANTATION OF THE HUMAN OVUM.—Prof. J. H. Teacher has contributed to the summer number of the *Journal of Obstetrics and Gynæcology* (vol. 31, No. 2) an important paper on the implantation of the ovum and the early development of the trophoblast in man. That the human ovum burrows into the uterine mucous membrane, parasite-like, destroying tissue and provoking inflammatory and reparative reactions, has been recognised for some years. This memoir contains an account of the further discovery that the closure of the decidua reflexa is effected by an apparatus developed from those ectoderm cells of the ovum which are the last to enter the mucosa tissue. This apparatus unites with the uterine epithelium and afterwards with the other tissue of the lips of the aperture through which the ovum has passed. For the complete structure the author suggests the term "operculum deciduæ." The recognition of this apparatus has led to the identification in the human ovum of a polar arrangement similar to that found in the hedgehog and in the guinea-pig. The ovum, therefore, may be described as having an entering or implantation pole and an adhering or closing pole, and it is this polarity which determines the position of the embryonic rudiment in the blastocyst and the situation of the placenta. The operculum, which differs from the Traeger of the rodent in taking no part in the formation of the placenta, usually becomes detached from the blastocyst when its function of closing the aperture has been fulfilled, a shield of fibrin being formed by thrombosis in the implantation cavity and so closing the passage from within. Prof. Teacher finds that the conclusion formerly arrived at by himself and Prof. Bryce that there are two generations of trophoblast (a primitive or implantation and a placental trophoblast) is entirely justified. These and many other cognate matters are dealt with in this memoir. It is illustrated by fifteen magnificent plates (some coloured), the cost of which has been defrayed by the Carnegie Trust for the Universities of Scotland. The material used in the investigation consisted of the original "Teacher-Bryce" ovum, first described in 1908, and a new human ovum of somewhat later age. The recent literature of the subject containing accounts of other early ova is referred to so as to facilitate a comparative study of the various processes described.

DIFFUSION AS A FACTOR IN ORE DEPOSITION.—In a paper on "Some problems of diffusion, with special reference to the study of ore deposits" (Science Reports of the Tohoku Imperial University, 3rd Series, vol. 2, Nos. 1 and 2, pp. 105-185), Manjirô Watanabé gives the results of some investigations on diffusion, amplifying the work done previously by Liesegang and others, but giving special attention to

the bearing of diffusion phenomena on ore genesis. Following Liesegang's method, experiments were made with gelatin media. Experiments were made also with kaolin, sand and calcium carbonate, in order to approximate more closely to natural conditions of ore deposition. As reacting materials, the sulphates, carbonates, nitrates and chlorides of common metals, sodium and barium sulphides, ammonia, and sodium carbonate or bicarbonate were employed. The velocity of diffusion with simultaneous precipitation was investigated, and a new equation proposed for the expression of diffusion velocity under these conditions. This equation is $x/\sqrt{z} = K(Z-z)/Z$, where z is the time and x the distance of diffusion, Z the time from the commencement of diffusion to the critical point of precipitation, and K is the velocity coefficient or the value of $x/\sqrt{z}$ at the commencement of diffusion. An examination of the magnitude of diffusion effects in Nature led to inconclusive results, but it is inferred that, contrary to the claim made by some previous workers, the effect of increased temperature in promoting diffusion is comparatively small; and that it takes more than 10,000 years for diffusion to take place over a distance of 100 metres. Other problems investigated include rhythmic precipitation, zonal or differential precipitation, and the action of various solutions diffusing into colloidal precipitates of metallic compounds. The order of stability of various sulphides in acid solutions, from more stable to less stable, was found to be as follows: silver sulphide, copper sulphide, lead sulphide, zinc sulphide and ferric sulphide.

The Economic Utilisation of Coal.—In the June number of *State Technology*, the journal of the Institute of Professional Civil Servants, Mr. H. E. Weaver has an article on coal, directing attention in simple language to facts long recognised by fuel experts but little appreciated by the general public: that this commodity is an ever-wasting national asset and that its combustion in open grates is little short of calamitous. The proper utilisation of coal lies in its scientific carbonisation, the refinement of its many and varied products, as in the case of petroleum, and their economic use under the best conditions in national, industrial, and domestic life. To a large extent the coal-gas industry has pointed the way, and there is little doubt that its development to its present important position is due not so much to the actual production of gas as a common form of heat energy, as to the numerous and invaluable by-products to which its preparation gives rise. As is well known, the products resulting from retorting coal can, apart from the gases evolved, be grouped into two main classes—tar and ammoniacal liquor; the former is the basis of a wide range of oils, including anthracene, themselves the starting-points for the production of benzol, naphthalene, cresols, creosote, anthracene, to mention only a few compounds; linked up to the refinement of these products are a host of distinctive technical processes resulting in the manufacture of motor fuel, explosives, disinfectants, preservatives, drugs, and perfumes (mainly from treating benzol, toluol or xylol), the production of dyes from naphthalene, with alizarine and further dyes from anthracene; the solid products in the form of pitch and other hydrocarbons are likewise capable of refinement for the particular purposes to which they are to be put. From the ammoniacal liquor are prepared the valued ammonium salts and ammonia itself, cyanides, and sulphur compounds. One has only to remember the significance of cyanide in the South African gold industry to realise its importance as a factor which has made that industry possible. There is, in effect, such a wealth of possibility in the lumps of coal which we casually put on our domestic fires, that our action must seem little short of desecration to the "spirit of coal," cleverly portrayed on the posters issued by the Gas Exhibit Committee at the British Empire Exhibition, to which, and also to the instructive gas exhibit, the author rightly directs public attention.

The Production of High-Velocity β-rays by the Action of Hard β-rays—M. J. Thibaud has studied the β-rays produced by bombarding U, Pb, W, and Ag with the high-energy γ-rays of RaC (*C.R.* Paris Acad. Sci., July 21). The following table gives in the first line the symbol of the element employed as secondary radiator, in the second the energy in kilovolts required to detach an electron from the K level, and in the following the energies in kilovolts of the observed β-rays.

U.	Pb.	W.	Ag.
117	89·3	69·5	25·6
1004	1034	1057	1100
1122	1151		
1650	1677		

When the energies in the first line are added to those in the following lines, the energies of the γ-rays liberating the β-rays are found to be 1123, 1241, and 1763 in kilovolts; a γ-ray with energy 605 kilovolts has been previously found. All the important lines of the high-velocity β-ray spectrum of RaC, with one exception, are due to a photo-electric effect of the penetrating large quantum γ-rays. When radium is in contact with another element, there are two corpuscular emissions, giving similar spectra more or less shifted with regard to one another, the first being about four times as intense as the second. This agrees with the view of Ellis that the atom emitting the γ-ray has the greatest probability of absorbing it, and producing photo-electrons.

Conductivity of Metallic Vapours.—Work has been done on the conductivity of metallic vapours in flames by a number of investigators, but Dr. E. Zachmann, in the July number of the *Annalen der Physik*, shows that a number of precautions which are necessary in order to measure the true conductivity have previously been neglected. He develops the theory and describes a very complete investigation of the vapours of the alkali metals. Two devices were adopted to prevent electrons from heated electrodes from penetrating into the flame; the hot surface of the Meker burner employed was made the anode, and electrons from it were driven back into it by the applied E.M.F.; the cathode stood above this, and was divided into a central portion of copper with a circular horizontal surface, surrounded by the horizontal surface of a metallic grid, which formed a guard ring; both portions of the cathode were water cooled. It was possible to adjust the flame so that, over a considerable vertical length, it could be shown that the field intensity was nearly constant. The probe electrodes employed were investigated theoretically and experimentally, and the best form for them was determined. It was found that the conductivity of the vapours of the alkali metals is proportional to the square root of the concentration in the flame, which agrees with the theory; it varies as the square root of the atomic weight of the metal, and increases rapidly with increase of temperature. It also appears that the production of electrons is almost entirely due to collisions between the metal atoms and the gas molecules of the flame, very few being due to collisions between two metal atoms.

Recent Industrial Research in Cotton.[1]

THE volume of memoirs before us includes eight summaries of the current literature on such properties of cotton and cotton materials as are studied in more detail in the majority of the twenty-three other original papers. Although the plant is the source of supply of raw cotton, it is strange that these memoirs contain only one summary of existing literature on the application of botanical knowledge to immediate cotton industrial needs. The reason is that little trustworthy literature on this important subject exists.

The summaries are well compiled, and the length of the appended bibliographies (one includes 200 references) illustrates the care taken in their production. They are invaluable to scientific workers, in cotton and other allied textile materials, who are outside the British Cotton Industry Research Association.

The original papers are contributions from the botanical, physical, chemical, and physico-chemical departments of the Shirley Institute. Papers on the measurable characters of raw cotton, the morphology of the cell-wall of the cotton hair—which embodies some excellent photo-micrographs—and the conditions causing, and the prevention of, mildew in certain dyed cloths, form the bulk of the contribution from the botanical side. It is stated that infection of a cloth with a moisture content of 7·8 per cent. developed in nine weeks. Since raw cotton will absorb this quantity of moisture on exposure to an atmosphere of 0·66 relative humidity, which is far below the average value for the Lancashire district, the oft-recurring appearance of mildew in the raw material is not surprising.

The physical papers on the behaviour of cotton yarns under alternating stresses are characterised by the enormous number of tests made. Periodic variations which have previously been established in yarns tested by continuous loading methods, are found, in many cases, either to have disappeared or to have been considerably modified. Also, as neither of the two methods of testing is directly applicable to the study of stress effects in cloth, it is very doubtful whether, at this stage, the results obtained from thousands of tests on the peculiarity of any one yarn, very often the product of poor workmanship or the effect of efforts to increase production in the mill, are worth the highly trained labour expended on them. The writer is well aware of the variability of yarns spun under the best conditions, but cannot this be paralleled in the large scatter of rounds about a target engaged by a gun well and truly laid? A good gunner knows well that a comparatively long bracket is sufficient information to enable him to register the target roughly, if many other targets are to be registered in a limited time. Later, the interesting targets are then given the further attention which appears to be adequate.

The physical papers on the rigidity and plasticity of cotton hairs are very carefully done. It is doubtful whether the determination in absolute units of the coefficient of rigidity of a cotton hair, with its characteristically open structure, can be justified, especially when the influence of the relative humidity of the atmosphere on the physical constants of the hair is almost ignored. The force required to bend a dry cotton hair is greater than the force to bend the same hair containing 20·0 per cent. of moisture, even though the wet hair has the greater cross-section. The work on the plasticity of cotton hairs is of much higher order, and the magnetic torsiometer employed in this investigation is a cleverly designed instrument, well suited to the continuous measurement of small forces.

Two good methods of measuring the lustre of doubled yarns are described. The first is a direct photographic, and the second a photometric, method, in which the intensity of the light reflected from the yarn is compared with the intensity of light transmitted through a ground glass screen, illuminated in a controlled manner. A satisfactory method of measuring the lustre of yarns has been much needed, and the definiteness of the results obtained with the photometric method is encouraging. The general utility of the investigation is marred by the absence of information on the mercerising process used in preparing the yarn, on which process the lustre of yarns so much depends.

The investigations on the chemical constituents of the benzene extract from American cotton, and the volatile products derived from cotton by the action of water and sodium hydroxide at 40 lb. pressure, almost lead one to ask whether there is anything which cotton does not contain. The detailed examination of the extracts reveals the skill and patient labour involved.

Braidy's method of determining the copper number of modified and unmodified cotton cellulose has been found satisfactory after critical examination. The application of the results of colorimetric and titrimetric methods of determining the quantitative absorption of methylene blue by cotton cellulose of varying purity to the control of the bleaching process, to the detection of oxidation of cellulose (over-bleaching), and to the distinction between some raw Egyptian and American cottons, is perhaps the most interesting of the chemical contributions. The absorption of methylene blue by cotton cellulose is shown to vary directly with the ash content, thus confirming the conclusions of Rona and Michaelis and opposing the views of Bayliss.

On the physico-chemical side, work on the properties of starches used in sizing yarns is described. The results of the investigation on the moisture-absorbing properties of thin films of cooked starch bear a striking resemblance to those obtained on the moisture-absorbing properties of cotton. The botanical origin of the starch is found to have no appreciable bearing on the moisture-absorbing power. In contradistinction to this, the viscous properties of pastes made from maize and farina starches are shown to differ considerably.

Using a more sensitive form of the Justin-Mueller turgometer, the swelling of cotton cellulose in sodium hydroxide solutions has been examined. Although this attempt to find a means of eliminating discrepancies due to differences in the visible structure of cotton hairs was not successful, some interesting structural changes are noted.

Although these memoirs are an encyclopædia of information on the measurable properties of raw, spun, and chemically treated cotton, there is comparatively little cross-connexion or generalisation. They might be compared favourably with a Greek temple in the first stages of construction. The foundations have been thoroughly explored, and a number of pillars have been begun at very short spacial intervals. We are hopeful that the superstructure will be worthy of the stoutness of the supports; meanwhile, those who are only interested in the commercial value of the knowledge can trust in this solidity until such time as the superstructure takes a form which they can recognise. F. P. S.

[1] Shirley Institute Memoirs, vol. 2, 1923. Pp. vi+394+v. (Manchester: British Cotton Industry Research Association, 1924.) n.p.

Orchard Heating in the United States.

MUCH progress has been made of late years in the study of fruit growing, especially with reference to orchard heating and the development of more accurate methods of predicting low temperatures and counteracting their damaging effects. Special information has been given in the U.S. *Monthly Weather Review* for different districts, notably for North Carolina, in Supplement No. 19, published last year; and the *Monthly Weather Review* for December last has an article on "Damaging Temperatures and Orchard Heating in the Rogue River Valley, Oregon," by Mr. F. D. Young, Meteorologist, and Mr. C. C. Cate, Plant Pathologist. Observations made in the past with regard to temperature are utilised by the authors.

The pear is the principal fruit crop of the valley, but so far less has been done in determining the damage by cold to this crop than to peaches, apples, and apricots. A large part of the article deals with the actual comparisons of the pear crops harvested from adjoining protected and unprotected orchards during the seasons of 1921 and 1922, and partially with 1923. The cold due to radiation with a clear sky is the special lowering of temperature dealt with. The upper and less protected parts of the tree feel the effect of radiation more fully. Fruit blossoms were examined and the extent of damage noted for the different exposures under examination, and from 150 to 350 blossoms were cut open and examined in determining percentages of damage at each count. The protected orchard is equipped with a various number of oil-heaters, ranging from about 9 to 250 2-gallon lard-pails to the acre. Graphs are given showing the range of temperature at unheated check stations and at heated orchards, the heating, in examples shown, making a difference of 4° to 8° F. The great value is clearly the maintenance of night temperature above the damaging point, say above about 30° F.

Excellent photographs are given showing the development of pear blossoms and fruit at different dates of progress, and of fruit in which the seeds have been damaged or undamaged by frost. Photographs also show the crop, in number of pears at different heights on the tree; for example — ground to 6 ft., 6-10 ft., 10-14 ft., and above. Also the cropping in boxes from respective trees in protected and unprotected orchards—ranging from more than 20 boxes to a single box—is given.

In one of the largest pear and apple orchards in the Rogue River Valley, orchard heaters have been used during the past thirteen years, and during that time the fruit crop has never been materially reduced through frost-damage. A rougher method of orchard heating was previously adopted, but it was far less efficacious.

Although the discussion under review deals only with the Rogue River Valley, it is stated that the effectiveness of orchard heating, where properly handled, applies with equal force in preventing damage by frost in Western Oregon and in the entire States of California and Washington. Detailed studies in southern California show that orange groves can be protected against outside temperatures of 18° F., and the protective value of heating is generally accepted by citrus growers throughout the State.

The economic phase of orchard heating has been intentionally ignored, although the authors give a few convincing facts in support of the cost incurred, and they note that, in the Pacific Coast States, orchard heating is generally practised only in the colder portions of each district.

University and Educational Intelligence.

LONDON.—Applications are invited for the William Julius Mickle fellowship of the value of at least 200*l.*, to be awarded to the man or woman who, being resident in London, and a graduate of the University, has in the opinion of the Senate done most to advance medical art or science during the preceding five years. Applications must be received before October 1 next. Particulars may be obtained on application to the Academic Registrar, University of London, South Kensington, S.W.7.

THE University of the Witwatersrand, Johannesburg, gives in its Calendar for 1924 an interesting sketch of its origin and development. From 1916, when the Witwatersrand University Committee was formed for the purpose of developing the South African School of Mines and Technology, first into a full University College and ultimately into a University, progress has been very rapid, the number of students in each of the years 1916 to 1923 having been: 77, 173, 191, 301, 635, 812, 983, 1106. The University, formally opened in October 1922, has now fully organised Faculties of Arts, Science, Medicine, Commerce, Engineering, and Law, and a teaching staff of a hundred professors and lecturers.

THE United States National Research Council has published in Bulletin No. 38, particulars of more than 400 foundations of fellowships and scholarships for advanced work in science and technology. The compilation is provided with a subject index which shows that about 170 foundations are for research in pure science, 140 for research in technology, and 65 for medical research. A comparison with Appendix xxiv. of the British Empire Universities Yearbook seems to show that it is a much commoner practice among American than among British universities to admit to candidature graduates of institutions other than those in which the fellowships, etc., are tenable. The practice has obvious advantages, especially in the case of a university which has achieved pre-eminence in the advanced teaching, or facilities for the advanced study of, one or more branches of knowledge. From one point of view it is complementary to the practice of giving travelling fellowships.

AN Education Week is being organised for November 17-23 by the United States Bureau of Education in co-operation with the National Education Association (representing the school teachers of the United States) and the American Legion. The celebrations are to be distributed over the week thus: Monday, Constitution Day—"The Constitution: the bulwark of democracy and happiness"; Tuesday, Patriotism Day—"The United States flag is the living symbol of the ideals and institutions of our republic"; Wednesday, School and Teacher Day—"The teacher: the guiding influence of future America"; Thursday, Illiteracy Day—"Informed intelligence is the foundation of representative government"; Friday, Physical Education Day—"Playgrounds and athletic fields mean a strong healthy nation"; Saturday, Community Day—"Service to Community, State, and Nation is the duty of every citizen"; Sunday, For God and Country Day—"Religion, Morality, and Education are necessary for good government." For each day, appropriate topics and slogans are suggested. Conspicuous among those for the first two days are the following: Revolutionists, communists, and extreme pacifists are a menace to our constitution's guarantees of life, liberty, justice, security, and opportunity; the red flag means death, destruction, poverty, starvation, disease, anarchy, and dictatorship; stamp out revolutionary radicalism.

Early Science at the Royal Society.

eptember 6, 1664. Sir Robert Moray produced a ter of Mons. Huygens, dated at the Hague, mention- g an instrument devised by him for measuring the locity of descending bodies; as also, a new observa- n concerning Saturn, made the last spring at Rome, Campani, viz., that the circle of Saturn had covered part of its sphere above, and had been covered ereby below, even with a little shadow upon the cle below, and upon the sphere above: which servation Mons. Huygens looked upon as confirm- g his system, which himself had made.

1666. Sir Theodore de Vaux presented a paper of lumineure which was recommended to Mr. Evelyn peruse. This gave occasion to mention that Mr. ovey had intimated, that, upon the society's desire, r. Peter Lely, Mr. Cooper, and Mr. Streeter would erhaps not be unwilling to communicate to them e several curiosities and varieties of painting. Thereupon it was ordered, that Mr. Povey, Mr. velyn [and others] should be desired to meet and nsider together what particulars were fit to inquire to, and thereupon to discourse with the said masters.

September 7, 1663. Dr. Wilkins put the company mind to improve their former consideration of aking an history of the weather, in order to build ereupon an art of prognosticating the changes ereof: And he suggested, that it might be re- mmended to some of the members of the society, to ake constant observations, at least of the most nsiderable changes of weather: in order to which, Mr. Hooke was desired to engage therein, which he id; and Dr. Wilkins undertook to recommend the ame to Dr. Power. It was also thought proper that Dr. Wren should be written to, to send to the society scheme of his weather-engine, formerly proposed, in rder to see whether it needed any addition or not. ir Kenelme Digby related, that Dr. Dee by a diligent bservation of the weather for seven years together, cquired such a prognosticating skill of weather, that e was, on that account, accounted a witch.—Mons. Huygens presented a paper from his father Mons. Zuylichem containing a description of a new kind of candlestick, by means of which, the candle upon it gives more light than two torches together, consumes ess wax, frees from the inconvenience of smoking in the narrowest room, and needs no snuffers. The paper was ordered to be translated from the French.

September 10, 1662. It was ordered, that at the next meeting experiments should be made with wires of several kinds of the same size, viz., silver, copper, iron, etc., to see what weight would break them; Mr. Croune being appointed curator of this experiment.—Dr. Wren was reminded of prosecuting Mr. Rooke's observations concerning the motions of the satellites of Jupiter.—A proposition was offered by Sir Robert Moray about the planting of timber in England, and the preserving of what was then growing.

September 11, 1661. Two committees were appointed to propound experiments, one consisting of Dr. Goddard, Dr. Wilkins [and others] for the city of London; and the other consisting of the lord Viscount Brouncker, Sir Robert Moray, Sir Paul Neile [and others] for Westminster.

September 12, 1679. There was a discourse about ways of vision, from the assertion of Mr. Hooke, that a man used to see things always inverted would in time judge, that he saw them as they are. Sir John Hoskyns remarked, that looking at the sun or stars through a small hole made in paper caused them to appear less than to the naked eye. Dr. Croune gave the reason of the sun's appearing bigger near the horizon from the dilating of the pupil.

Societies and Academies.

PARIS.

Academy of Sciences, August 4.—M. Guillaume Bigourdan in the chair.—A. **Lacroix**: A new type of meteoric iron found in the desert of Adrar, Mauritania.—F. E. **Fournier**: An unpublished safety manœuvre for preventing collisions between steamships during fog.—A. **Haller** and R. **Cornubert**: Study of two symmetrical and unsymmetrical dimethylpentanones. Symmetrical dimethylcyclopentanone condenses with benzaldehyde in the presence of hydrochloric acid, giving a compound $C_{21}H_{22}O_2$: the unsymmetrical dimethylcyclopentane behaves differently, giving a true benzylidene compound.—Gabriel **Bertrand** and Hirosi **Nakamura**: A new case of physiological mutation in mice.—P. **Sergesco**: Some inequalities of Landau and Lindelof concerning monogene functions.—J. **Cabannes** and A. **Lepape**: The diffusion of light by krypton and xenon. The polarisation of the light diffused transversely by a pure inert gas is not total.—J. **Guinchant**: Rôle of the atmosphere in the propagation of Hertzian waves. Effects analogous with mirage in the case of light waves can be produced with Hertzian waves. The state of the lower atmosphere may be an essential factor in the propagation of radio-telegraphic waves. The changes in intensity and of direction of the waves, the differences in receiving during day or night, and influence of the seasons may be readily explained by normal meteorological variations.—André **Job** and René **Reich**: The catalytic activation of ethylene by organo-metallic nickel. A solution of phenylmagnesium bromide, to which a little anhydrous nickel chloride has been added, rapidly absorbs large volumes of ethylene. Subsequent addition of water gives ethane, ethylbenzene, styrolene and diphenyl, but no benzene.—H. **Gault** and Mlle. M. **Urban**: The soluble cellulose esters of the higher unsaturated fatty acids.—Max. and Michel **Polonovski**: The nitroso and benzoyl derivatives of eserine.—Ch. **Maurain** and L. **Eblé**: A photographic recording seismograph with three components.—MM. **Rothé**, **Lacoste**, **Bois**, Mlle. **Dammann** and Mme. **Hée**: Study of the propagation of the La Courtine explosions.—E. F. **Terroine**, Mlle. S. **Trautmann** and R. **Bonnet**: The energy yield at the expense of the carbohydrates in the growth of the higher plants.—L. **Emberger**: Cytological observations on the bulb of *Lilium candidum*.—M. **Couvreux**: New observations on the photomotor reflex.—P. **Vlès**, P. **Reiss** and E. **Vellinger**: Potentiometric measurements of the P_H of the substance of the eggs of the sea-urchin. For the crude egg substance, the P_H appears to be between 5 and 5·5 before loss of carbon dioxide; it rises to about 6·2 when this gas has been eliminated.—Ch. **Dhéré**, A. **Schneider** and Th. **Van der Bom**: The photographic determination of the fluorescent spectra of hæmatoporphyrine in various solvents.—J. **Régnier**: The variation of the anæsthetic power of cocaine hydrochloride as a function of the proportion of hydrogen ions. The rapidity of anæsthesia is much more rapid for alkaline than for acid solutions. With high P_H, anæsthesia is complete in two minutes.

August 11.—M. Guillaume in the chair.—A. **Lacroix**: The meteoric irons of Senegal and the Sahara.—A. A. **Guntz**: The energy set free in phosphorescence.

CALCUTTA.

Asiatic Society of Bengal, August 6.—Satya Churn **Law**: *Parus major cinereus* breeding in the 24 Perghanas. Two instances of the breeding of this

bird in the suburbs of Calcutta in the district of 24 Perghanas are recorded. Hitherto there was nothing on record about its nidification in this district.—Satya Churn **Law**: Kālidāsa and the migration of birds. Migration may not have been understood by Kālidāsa, but the phenomenon itself did not escape him. Scattered about in his works are passages which unmistakably refer to this peculiar feature of bird-life, and there are many expressions relating to birds which can be explained only with reference to the migratory phase of their life.—Bisvesvar **Bhattacharyya**: The age of the Padmā. Literary and historical argument in support of the thesis that the Padmā or lower course of the Ganges grew to its present size not during the 16th century A.D., as commonly held, but perhaps during the 14th, or even 13th, century.—Bimala Charan **Law**: The Aśmakas or Assakas in ancient India. A discussion regarding the name and origin of the Assaka tribe and a brief account of its traditional history as may be gleaned from Brahmanical and Buddhist literature.—J. H. **Hutton**: Some carved stones in the Dayang Valley. Descriptive of a little-known group of carved menhirs at Kasomari-pathar near Jamugiri, hitherto only known from a brief description by Bloch in 1905. A connexion may exist between the stones and surviving ceremonies of the Naga tribes.—A. **Grignard**: Our Romanised Hindustani-English dictionaries: their partial inefficiency and its remedies.—Lily **Strickland-Anderson**: Some notes on the customs of the Khasi people of Assam.

Science and Religion.

THE assembly of the Conference of Modern Churchmen at Oxford at the end of last month, and the adoption of the subject "The Scientific Approach to Religion" as the theme of the discussions, seem to suggest the present as an opportune moment for reconsidering the old question of the relation between scientific and religious doctrine. The atmosphere of this clerical conference was totally different from that of other ecclesiastical congresses where scientific questions have been under discussion. There was an almost complete absence of traditional presuppositions —in fact, there seemed to reign a determination to get back to first principles, and build upon the same foundation as that on which scientific teaching is based, namely, the ultimate nature of things—in a word, the structure and meaning of the universe.

The functions of religion and science are different both theoretically and practically, but it seems to us that both are equally necessary for the welfare of the human race. Religion differs in its theoretical aims from science, because the aim of science is the constant pressing forward to the discovery of new truth, whilst that of religion is the holding fast and transmitting to posterity of truth that has already been ascertained. On the practical side, the object of science is to adapt man ever more closely to his environment, and, so far as he can master it, to adapt the environment to him, whilst that of religion is to furnish the sanctions for the laws which hold society together. It may perhaps be objected that the delights of scientific investigations are able to support the man who pursues them in all the troubles of life without any assistance from religion whatever. This is undoubtedly true, but it does not carry us very far. For scientific work is impossible except in the environment of a civilised society, and the carrying on of such a society implies the performance of a great deal of monotonous and uninteresting work. The attempt to crush religious belief, and thus to persuade those who perform this work to persevere in the absence of the comfort and hope supplied by the Church, has proved a disastrous failure every time that it has been attempted. We have just witnessed the last of these attempts, that of the Bolshevists in Russia, which has resulted in consequences patent to all the world.

The conference was opened by an address by the president, the Very Rev. W. Inge, Dean of St. Paul's, who is distinguished above most other Churchmen by his knowledge of and sympathy with science, and it was closed by a sermon delivered by Canon Barnes, Bishop-designate of Birmingham, who was an eminent

scientific man and a fellow of the Royal Society before he entered the service of the Church.

If religious beliefs are founded on an ineradicable element in human nature, then nothing can be more disastrous than an irreconcilable cleavage between these beliefs and the teachings of science. It is, as Dean Inge said, an "open sore," and he added that to contribute in some measure to the healing of the sore was the main object of the conference. But religious truth is necessarily expressed in terms of the "Weltanschauung" of the period at which it was first promulgated. This "Weltanschauung" is just the science of the time, and as it becomes changed the religious truth is left embedded in a setting of outworn ideas. The aim, therefore, of the reconciler must be to extract the "timeless element" in religion from this setting and express it, so far as possible, in a pure and unadulterated form. This element Dean Inge finds in the "values"—goodness, truth, and beauty. These he declares to be the most real things in the universe: from their permanence he deduces not only the existence of God in whom they are completely realised, but also the permanence of those elements in us which respond to these values and seek for their complete expression.

Profs. Haldane and MacBride were invited to the conference as respectful and sympathetic outsiders, in order to state as clearly as possible the modern positions on vitalism and evolution. Prof. Haldane emphatically asserted that the action of living beings cannot be explained upon mechanical principles—it is theoretically possible to construct a series of imaginary machines the working of which will simulate more or less closely the actions of living beings; but as our knowledge of the details of these actions grows, so the machines become more and more complicated—and the futility of the whole procedure is shown by the fact that no account whatever can be given of the "mechanism" by which these machines come into being or how these supposed intricate structures emerge from the egg. Prof. MacBride pointed out that the acceptance of evolution necessitated the entire recasting of the Mosaic cosmogony and of the doctrines of sin and the fall set forth by St. Paul, and he also directed attention to the great outstanding difficulty in the way of any theory of a beneficent Author of the universe, namely, the cruelty and carnage involved in the elimination of the unfit. On the other hand, whilst giving a résumé of the well-known evidence for animal evolution, Prof. MacBride pointed out that "natural selection" gives no explanation of the process any more than the pruning-knife can account for the forces of growth in the plant; that the driving force of evolution is the power of the living being to rise up to meet adverse circumstances and, adapting itself to them, to overcome them; and th the powers acquired by the parents are transmit to the children. Evolution, therefore, in the pro sense, is a vital phenomenon which can be exhibi only by living beings, and to use it to include t physical and chemical processes involved in the cooli of a heated globe, for example, as did Herbert Spenc is to empty it of its essential meaning. In princip therefore, Prof. MacBride and Prof. Haldane agreed

The president in his opening address had touch on the limitations of scientific explanations. Scien knows nothing of origins or ends but only of process In a rigidly defined mechanical system, change a adaptation are impossible; moreover, if the cosm as a whole is regarded as a mechanical system, th it is not self-explanatory, for it is not a static syst but is "running down." No reason can be assign why it should not have already reached equilibrium we postulate an indefinite period of past time. The must be something permanent behind it—and th something which the religious soul quests for, a to which it believes itself to be akin, is God. Pr De Burgh's paper connects at this point with I Inge's address; for he dealt with the stupendo subjects of God, time, and eternity. In a most brillia essay he pointed out that the idea of time as a me flux of vanishing "nows" is inconceivable and se contradictory—that there must be a permanent ba underlying it, and this permanent basis he identifi with eternity. He thought that whilst an "Absolute of some kind was a necessary postulate of reason, required the religious experience to convince us the existence of God. This we think rather dangero reasoning. The word "God" is just the name giv by the plain man to the reality behind the compl of circumstances surrounding him, by which he limited and controlled. He is conscious of stron desires, and conceives purposes in the execution which he is frequently frustrated; therefore in th world around him there is an "other" to which h is frequently opposed. On any theory of evolutio his own nature and personality have somehow bee evolved out of this "other." Can the stream ri higher than its fountain? "He that planted the ea shall He not hear?"

Of course, it may be objected that these searche for the ultimate, these aspirations after union wit the divine, can never give us anything but pleasan dreams, whereas science supplies us with solid fact on which we can depend. This contrast between th certainty of science and the vagueness and uncertaint of religion sounds obvious, but we are not at all sur that it will stand critical examination. After al

hat are "facts"? "The ordinary man," said that ute philosopher McTaggart, "thinks that he knows cts; but when we analyse these 'facts' they turn it to be a compound of sensations and thoughts." is vain for the physiologist to point out that con- iousness appears in Nature as a mere epiphenomenon ssociated with the chemical changes in certain organic mpounds. When he uses reasoning like this, he nplicitly separates his own reason and perception om the rest of the world, and views the workings f other conscious beings from the outside. "I can- ot conceive of matter," said the candid Huxley, apart from mind to picture it in." To quote another ambridge philosopher: "From one point of view onsciousness appears a temporary phenomenon associ- ted with certain forms of matter, but when we look t it from another point of view it swallows every- hing else. Both views are true, and we do not ealise what a wonderful universe we dwell in till we ave grasped this fact."

Religion is sometimes regarded from the evolutionary oint of view as a defence mechanism which has been rought into being to support and encourage the ommunal life of the tribe, but reason and its product cientific knowledge may, with equal justice, be regarded as a food-getting mechanism evolved to enable us to feed ourselves, and in no way to be considered as capable of giving us accurate information about the universe. Indeed, if we for a moment assume the validity of our own sensations and view our fellow-man from without, what ground have we for supposing that his sensations will give him any accurate picture of the world around him? How can a vibration in the ether impinging on a retinal cell and setting up therein chemical changes which result in the "stimulation" of a nerve cell, and the transference of this "stimulation" to the brain, give any information as to the nature of the body from which the vibration proceeded? Yet, if we do not make this assumption, there is an end to science. If we, therefore, following our natural instincts, trust our senses to tell us what the universe is like, why should we not trust our religious instinct as to the kinship between our own spirits and the Ultimate Reality? The question, therefore, of the "validity" of our knowledge must be separated from all speculations as to its evolutionary origin.

The fundamental difficulty of the whole situation is that the man of science and the philosopher alike strives each to construct a complete system to include the whole universe. The humbler and more correct attitude is that of Huxleyan agnosticism, which, as Prof. MacBride pointed out at the conference, is entirely compatible with the Christian faith; for this faith is a determination to stake everything on the hope that the "values" will turn out to be real and eternal. In the obituary notice of Huxley published in NATURE and written by his pupil, Sir Michael Foster, there appears the sentence, relating to the problem of the survival of the soul, "Huxley was convinced that science could never with all its endeavours avail to raise one corner of the veil concealing that dream by which our life is rounded."

Perhaps we may best sum up the whole matter in the words of that scientific theologian, Harnack:

"In spite of intense effort our modern thinkers have not succeeded in developing a satisfactory system of ethics and one corresponding to our deepest needs on the basis of monism. They will never succeed in doing so. If this be admitted it is in the last resort a matter of indifference with what names we designate the two sides of the dualism which, as moral and thinking men, we encounter—for instance God and the World, Here and Hereafter, Visible and Invisible, Matter and Spirit, Necessity and Freedom. Unity can be *experienced* and one side can be subordinated to the other, but this unity is always reached by a struggle in the form of an endless problem which can only be approximately solved, and never by the refinement of a mechanical process. We are not able to bring our knowledge of time and space into the unity of a consistent Weltanschauung with our inner life. Only in the peace of God which is higher than all reason can we catch a glimpse of their ultimate unity."

The Rarer Elements.

Chemistry of the Rarer Elements. By Prof. B. Smith Hopkins. Pp. vii + 376. (Boston, New York, Chicago, and London: D. C. Heath and Co., 1924.) 15*s.* net.

THE reader's interest will be aroused even before he has opened this volume; for he will doubtless be curious to learn which members of the elemental series the author has decided to group together under the rubric of "rarer elements." The preface furnishes a satisfactory definition. Prof. Hopkins has taken as his province "those elements which are little known either because of scarcity, neglect, or ignorance." His object has been "to call attention both to the advances which have recently been made in our knowledge and also to the need of further research in the development of many of the less familiar elements."

It must be confessed that, to the non-specialist, many of the books hitherto written about the rarer elements are more than a little dry. Before opening them, the would-be reader has a foreboding—often justified in the event—that he will find within the covers simply the usual accumulation of facts carefully grouped under certain set headings: facts, individually

important, which seem to resist any attempt to force them into any far-reaching and logical scheme. This apparent incoherence of the data attains its culmination in the case of the rare earth group, where, although the proper elemental sequence is indisputable, no generally accepted system has yet been evolved which will bring the elements into line with each other or with the remaining forms of matter which we know.

There is another pitfall in the path of a writer upon the rarer elements. Owing to the fact that he is making an arbitrary selection from the material, he runs a grave risk of isolating the elements with which he deals from their commoner brethren; and in this way he tends to produce the impression that these rarer elements stand in a class by themselves, that gallium, for example, is in some mysterious way to be mentally segregated from the remainder of its group.

Prof. Hopkins's book avoids both of these difficulties. He gives the reader a general description of the salts of each of the elements with which he deals; but he has resisted the temptation to insert data simply because they are known. The result is that his book holds the reader's interest without difficulty, even in those places where dulness might be expected to supervene.

Even more praiseworthy is the fact that he never allows the student to forget the relations existing between the elements as a whole and the particular one which is under discussion. The book opens with a chapter on the Periodic System, in which some of the recently suggested forms of the Periodic Table are described and the possibility of further discoveries of new elements is examined. This forms the frame into which the rarer elements are fitted one by one. But, in addition to this, each section of the book is headed by an excursus in which a general survey is made of the group containing the special rare elements under discussion in that section. Thus the peculiar mental partition between the "rarer" elements and the "commoner" elements is never allowed to grow up in the mind of the student.

Another feature which makes the book specially valuable to the student is the way in which the practical importance of the rarer elements is emphasised in detail; for in some books the impression is left that these substances are mainly of academic interest. Prof. Hopkins, without overloading his pages, has succeeded in tracing the ramification of these rarer elements into commercial practice; and his chapters cannot fail to suggest that we are as yet only on the frontier of a great development. As a rule, the author deals in turn with the history of the element, its occurrence in Nature, its extraction and metallurgy, its properties, its uses, and he terminates his sections with brief descriptions of the more important compounds and the methods whereby they may be identified.

The publication of books of this type seems to be one of the hopeful features of modern chemical literature. In the past there was an appreciable gap between the college text-book on one hand and, on the other, the German compendium in six or more volumes which generally, with quite unconscious humour, was entitled a "Hand-book"; and the student who had just mastered the elements was apt to be intimidated when faced with his next step in the literature of his subject. Nowadays, with excellent series of monographs from British and American publishers, the student is much better off. He can get his information on certain subjects without having to wade laboriously through huge systematic "text-books". Thus he is able to attain a reasonable standard of knowledge without being discouraged by the force of realisation of how much he does *not* know; while at the same time his interest is sharpened and he is encouraged to go forward in the pursuit of a more complete knowledge. Chemistry, with all its modern ramifications, has long passed the stage when any one except the mere book-worm can pretend to "know" the whole of it in detail; and the recent trend in chemical literature away from the cast-iron systematic text-book has been all in the interest of the student who has just completed his course and is looking forward to extending his knowledge. Books like that of Prof. Hopkins are to be welcomed. A. W. S.

Geology of the United States.

A Text-Book of Geology: for Use in Universities, Colleges, Schools of Science, etc., and for the General Reader. By Prof. Louis V. Pirsson and Prof. Charles Schuchert. Part 2: *Historical Geology.* By Prof. Charles Schuchert. Second, revised edition. Pp. ix+724. (New York: J. Wiley and Sons, Inc. London: Chapman and Hall, Ltd., 1924.) 22*s.* 6*d.* net.

ORIGINALLY published nine years ago, Pirsson and Schuchert's Text-book has become the most popular introduction to geology among American students, and its well-merited supremacy is now likely to be still more firmly established by the issue of a second edition in which it has been thoroughly revised and brought up-to-date. The first volume, by the late Prof. Pirsson, deals with physical geology and is naturally of wider interest than the second part—now under review—in which Prof. Schuchert lucidly sets forth the principles of stratigraphy and palæontology and the broader features of the geological history of

United States. Compared with its first edition, second volume is now increased by about eighty ges, a series of palæogeographical maps have been roduced, and the Ozarkian has disappeared as a stem, the formations known by that name being now garded as the closing epoch of the more familiar mbrian. Eozoon is still thought to represent the rliest known evidence of calcareous algæ. As in the st edition, there are no detailed references, but this fect is met by appending to each chapter a list of ggestions for further reading. It is worthy of notice at British work has not been neglected as it so often in American books. Moreover, the Period names e retained for the most part in their original forms, d such terms as "Permic" are happily given no pport.

The treatment of the work as a whole is very much oader than the title indicates, for interspersed with e stratigraphical chapters there are just as many aling with palæontology. These, with others of neral interest, on such topics as astronomy, biology, d evolution, make up a composite course of about rty-five lectures.

In teaching historical geology, it is logically but unrtunately necessary to plunge straight away into the tricate labyrinth of the Archæan; to start as closely possible to that vague "beginning" of which Hutton uld find no certain trace. The difficulty is one, owever, that can be fairly met and overcome. But und scientific method becomes impossible when the bject is made to begin with the origin of the earth d its "pre-geological" history. These are problems at belong more properly to geophysics, problems hich will be attacked with success only when the rth's age, its thermal history, the origin of the ntinents, and other fundamental questions have been lved with a greater degree of confidence than is yet ssible. It will nevertheless be refreshing to British aders to find that the influence of the planetesimal ypothesis and of its author's more personal opinions now apparently steadily waning. This is mainly the sult of criticisms by Daly and Barrell, the latter, efore his lamented death, having clearly influenced he teaching of the book. Although no mention is ade of the work of Harold Jeffreys (whose new book n geophysics leaves no excuse for that omission n future), the conclusion that the earth must have assed through a fluid state is accepted for other easons.

A very interesting chapter deals with the perennial uestion of the permanency of the continents, but the roblem of their origin is not solved by the speculations ffered. The difficulty is essentially to explain the teral differences of density between the lighter continental and the heavier oceanic segments of the earth's crust. It is suggested that heavy flows of widespread magma broke through the crust over wide areas and caused them to subside into ocean basins; but unless the magmas were very much more dense than we have any reason to suppose, the new surface would be no lower than the original one, and the vertical distribution of densities would be unstable in a way that should since have disclosed itself in the petrology of the oceanic igneous rocks. Pushing the light rocks down to great depths does not solve a problem, which is one of lateral, not vertical, differences.

Other general chapters deal with coal, petroleum, geological climates of the past, man's place in Nature, and the age of the earth. Joly's recent views based on pleochroic haloes are referred to but not accepted. Schuchert concludes that the hour-glass of denudation and sedimentation has not been read correctly by the majority of geologists in the past, and that the earth is at least 500 million years old.

Regarded as a college text-book, perhaps too much space is devoted to speculative matters and not enough to the economic resources of the systems or the igneous history of the continent, though these aspects of the subject are by no means wholly neglected. The stratigraphical chapters naturally take their main inspiration from the country of the author, and little attempt is made to correlate with Europe. The appeal of the book is therefore limited from the point of view of the British student, for whom, indeed, it is unsuitable as a text-book. It is, however, full of ideas for teachers of the subject; it may be confidently accepted as the most up-to-date and authoritative summary of the geology of the United States; and it is consequently worthy of a place in every reference library.

ARTHUR HOLMES.

Co-ordination of Numerical Data.

The Calculus of Observations: a Treatise on Numerical Mathematics. By Prof. E. T. Whittaker and G. Robinson. Pp. xvi+395. (London, Glasgow and Bombay: Blackie and Son, Ltd., 1924.) 18*s*. net.

A SET of numerical data, whether obtained from theory or experiment, gives rise to mathematical problems of interest and importance. The consideration of these problems now forms an important branch of pure mathematics: apart from this, some knowledge of them is required by workers in many fields —astronomers, meteorologists, physicists, engineers, naval architects, actuaries, biometricians, and statisticians. Until recently the subject has received but little attention in the mathematical departments of

British universities. During the last ten years, however, interest in it has been thoroughly aroused, especially in the Universities of London and Edinburgh. To Prof. Karl Pearson, head of the Department of Applied Statistics at University College, London, is due the credit of organising a mathematical laboratory for dealing systematically with numerical problems. During the War, Prof. Pearson's laboratory was occupied with numerical work on ballistics: more lately it has produced a series of tracts on computation. In Edinburgh, Prof. E. T. Whittaker has also organised a mathematical laboratory, and the volume before us may be regarded as a manual of the methods that have been evolved there.

The first four chapters, on interpolation and difference formulæ, are also published as a separate tract under the title "A Short Course in Interpolation" (price 5*s*. net). To a mathematician this section is much more convincing than those accounts of the subject which aim primarily at the application of interpolation to engineering or actuarial work. In particular, the important chapter on divided differences has not, we think, appeared before in any English book. Some of the early worked examples involve fifteen-figure numbers, and seem unnecessarily heavy: all the principles at stake could be amply illustrated by numbers of seven or eight digits.

The long sixth chapter gives an account of many useful methods of obtaining the numerical solution of an algebraic or transcendental equation. In numerical work, Horner's process of successive approximation is often found to be less useful than the root-squaring method of Graeffe. Graeffe's method, unlike Horner's, is easily adaptable to the location of complex roots—a problem the importance of which has greatly increased of late through its occurrence in determining the stability of an aeroplane. When an algebraic equation has only one or two pairs of complex roots, Graeffe's method is sufficient to isolate them without difficulty. A recent modification of the method, due to Prof. Brodetsky and Mr. Smeal, enables any number of complex roots to be located: we hope that this discovery will be added to the next edition of the work under notice.

Only the first seven chapters will normally be read as part of a university undergraduate course. A separate volume containing this part of the work alone would appeal to a wide class of readers. The rest of the book, from Chapter viii. onwards, forms an introduction to the mathematical theory of statistics, which, normally, will be read only by graduates engaged on research. Compared with the first seven chapters, this part of the work is too heavy, and the introductory matter leading up to it is inadequate.

When the Edinburgh laboratory was founded in 1913, a trial was made, so far as possible. of ev method which had been proposed for the solution the problems under consideration, and many of th methods were graphical. During the ten years t have elapsed since then, the graphical methods h almost all been abandoned, as their inferiority become evident, and at present the work there almost entirely arithmetical. No previous book any language contains the matter collected here a ten years' experience of dealing with numerical da The authors are to be heartily congratulated successfully producing a book that gives the result so much pioneering work. W. E. H. B

Our Bookshelf.

Emergency Water Supplies for Military, Agricultu and Colonial Purposes: Based on Experience of Mediterranean Expeditionary Force Operations, w Special Reference to the use of Drive Tube Wells a Drilling. By A. Beeby Thompson. Pp. xii + 18 45 plates. (London: Crosby Lockwood and S 1924.) 21*s*. net.

Possibly no problem is of such vital importance the pioneer and settler as that of the location o suitable source of water supply for drinking and pota purposes; scarcely less inevitable is the problem connexion with military incursions into countries wh are destitute of uncontaminated surface supplies a ill-suited for overland transport. Therefore, to classes of adventurers and explorers, whether prospe ing, colonising, or expeditionary, Mr. Beeby Thompso book, with its valuable record of methods and c trivances used in connexion with the Mediterran Expeditionary Force operations, will come with w come interest, affording much practical precept a useful advice.

Upon diviners or dowsers, Mr. Thompson looks w sceptical eyes. He allows some to be honest, but frankly suspicious of them all and their metho Their inconsistencies, not less than their failures, fill h with distrust; yet he is not above letting them hav trial. "In the absence of any definite scientific reas for locating a well at a particular spot, the dow could be given his chance, and to the author's knc ledge the location of small supplies has resulted several occasions." Mr. Thompson is certainly fair.

The book proceeds, however, on a more scient basis than any which governs the dowser in his pr nostications. The origin of water is discussed, t incidence of rainfall, the amount of run-off, the le of water tables, sources of potable water, and the va of hygienic measures; and thereafter follows a ser of chapters on the driving of tube wells, drilling ope tions, pumping equipment and water analysis, w illustrations from actual experience in Bulgaria, Serl (why does the author write Servia ?), Macedonia, a elsewhere. Full of practical direction and experimen information, the book should be a valuable guide to

o seek water supplies in unexplored or undeveloped ions.

Mr. Thompson comments on a fact which he states racted notice and inquiry during the War, namely, he comparative permanence of springs high up on ountain ranges after long periods of drought when ose lower down commenced to fail," and he advances e reasons, separately or collectively, to account for e phenomenon. It would be interesting to know the tent to which this characteristic was observed and nether it was so general as to be really remarkable.

BRYSSON CUNNINGHAM.

he Plant Alkaloids. By Dr. T. A. Henry. Second edition. Pp. viii+456+8 plates. (London: J. and A. Churchill, 1924.) 28*s.* net.

WHEN Dr. Henry published the first edition of his Plant Alkaloids" ten years ago, general satisfaction as felt and expressed at the appearance in English a really comprehensive work on so important a ubject, and at the masterly way in which the author ad dealt with it. Since then, notwithstanding the eneral interruption of such work due to the War, any investigations have been made and many searches published on the isolation, constitution, nd properties of the alkaloids. One need only ention such examples as the investigation of the lkaloids of ergot, opium, areca nut, pomegranate ark, belladonna, cinchona, Calabar bean, ipecacuanha, ohimbe bark; of the oxidation products of brucine y Leuchs and his collaborators, of the constitution f chelerythrine by Karrer, of chelidonine by Gadamer, nd so on, to realise the immense amount of material nat Dr. Henry had to examine critically and sift in ne preparation of the second edition of his work. Ie has succeeded admirably. Researches published n the spring of this year have received attention, lthough it may not have been possible for him to eal with them so fully as he may have desired.

Notwithstanding the large amount of fresh material o be dealt with, the size of the volume has not been ncreased, as that which had been superseded has een omitted as unnecessary. Methods of determin- ng the percentages of alkaloids in drugs have received ather less attention than formerly, and rightly so; ndeed, it is rather to be doubted whether these could ot in the future be relegated entirely to the books hat make such assays the subject of special attention. On the other hand, rather more space has been devoted o the discussion of such information as is available n the relation of chemical constitution to pharmaco- ogical action, a subject of surpassing interest but ne in which it is not yet possible to draw general conclusions. The six pages given to the pharmacology of the tropane group is a good example of the clear nd concise manner in which the author deals with his difficult problem.

Dr. Henry is to be congratulated on the successful accomplishment of his task. All who are interested in plant chemistry in general, or in the plant alkaloids in particular, will be glad to have at their disposal a work of reference that is thoroughly up-to-date and as trustworthy in its information as it is possible for such a work to be.

Handbook of the British Flora: a Description of the Flowering Plants and Ferns Indigenous to, or Naturalised in, the British Isles; for the Use of Beginners and Amateurs. By George Bentham. Revised by Sir J. D. Hooker. Seventh edition, revised by Dr. A. B. Rendle. Pp. lxi+606. (London: L. Reeve and Co., Ltd., 1924.) 12*s.* net.

THE publication of a new edition of Bentham's "Handbook of the British Flora" is of considerable importance to students and teachers of botany in Great Britain. There is no published work which better serves as an introduction to the British flora than this, and, though it can be strongly urged that we now need a completely new "Handbook," approximately on the lines of Schinz and Keller's "Flora der Schweiz," it is a good thing that the republication of Bentham and Hooker's Handbook has not been undertaken without a revision.

Dr. Rendle has most decidedly improved the work, and in many respects has made it more in accordance with modern knowledge and usage. The nomenclature now approximates—after allowing for very considerable differences in species standards—closely to that of Babington's "Manual" (10th edition). The chapter in the introduction on vegetable anatomy and physiology has been omitted, the etymology of generic names and indications of pronunciation have been added, while certain improvements have been made in classification, particularly of the Cryptogams. Descriptions of the relatively few additions, since the last revision, of "Benthamian species" to the British flora are inserted, and bibliographical references are given to some of the more important recent researches on the critical genera. In spite of these improvements, it seems a pity that the very "large" species standard has been retained even for the use of "beginners and amateurs." Modern field-botany tends so much towards ecology, and systematists often feel that the determination of species by ecologists is none too critical, that the need of a handbook with complete keys and adapted for field-work, but based on a conception of smaller, and often more actual, species, is greater than ever.

La Photographie des couleurs. Par Prof. J. Thovert. (Encyclopédie scientifique: Bibliothèque de Photographie.) Pp. viii+300+4 planches. (Paris: Gaston Doin, 1924.) 17·60 frs.

THE photography of colour is a subject that has been gradually growing in importance and extent during the last few decades, so that the time has come when it may well be treated of in more detail than is possible in moderate-sized manuals of photography in general. This volume is therefore a welcome addition to photographic literature. The author deals first with light and colour, including the transmission, refraction, diffraction, interference, and absorption of light, the production of spectra and their uses, and wave motion. The reproduction of colour by interference, dispersion, and by three-colour and two-colour methods follows, with practical instructions and theoretical considerations. Processes that have only a classic or historic interest are treated of sufficiently, but the special adaptation of methods to photomechanical processes is not included. The book is well and usefully illustrated, and has four good plates in colour.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Assignment of Lines and Term Values in Beryllium II and Carbon IV.

We have already published briefly the methods by which we have recently been able to determine with certainty the degree of ionisation of the atoms giving rise to many of the lines of the spectra produced by our "hot sparks," and in the case of Boron III the method by which the "Term Values" have been worked out (Proc. Nat. Acad., May 15, 1924. See also forthcoming articles in *Physical Review* and *Phil. Mag.*).

The object of the present note is to make a preliminary report upon the application of the same methods to the determination of the chief characteristics of the spectra of the "stripped atoms" of beryllium and carbon (Be_{II} and C_{IV}).

TABLE 1.

BERYLLIUM II.

Int.	λ I.Å. Vac.	ν Vac.		Term Values.
1	1512·31	66124·0	$(2p_2-3d)$	$4f$ − 27438·5±3
2	1512·45	66117·9	$(2p_1-3d)$	$3d$ − 48826·1±3
1	1776·27	56297·7	$(2p-3s)$	$2p_1$ −114943·7±3
1	4675·6	21387·6	$(3d-4f)$	$2p_2$ −114950·3±3
?	3132·086	31927·60	$(2s-2p_2)$	$2s$ −146877·9±3
?	3131·438	31934·21	$(2s-2p_1)$	$3s$ − 58649·3±3

TABLE 2.

CARBON IV.

Int.	λ I.Å. Vac.	ν Vac.		Term Values.
2	384·4	260166	$(2p-3d)$	$3d$ −195333±30
1	419·8	238197	$(2p-3s)$	$2p_1$−455445±100
4	1548·26	64588·6	$(2s-2p_1)$	$2p_2$−455553±100
4	1550·84	64481·2	$(2s-2p_2)$	$2s$ −520034±100
				$3s$ −217302±100

With the aid of the foregoing term values, and those which we have already published for stripped boron (B_{III}), it becomes possible to arrange tables for the stripped atoms Li_I, Be_{II}, B_{III}, C_{IV}, precisely similar to those which Pashen and Fowler have arranged for the series Na_I, Mg_{II}, Al_{III}, Si_{IV}. Such tables (3 and 4) follow.

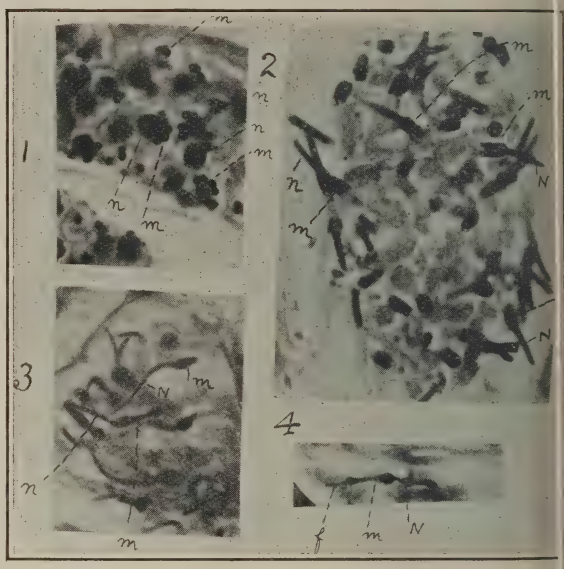
The Scorpion Spermateleosis.

In two recent letters to NATURE (July 12 a August 2) Mr. Vishwa Nath has referred to the resu obtained by two of my students. Mr. Nath fir himself unable to support the statement of Pr Bhattacharya and myself, that in the scorpi spermateleosis "the mitochondria form the spe tail directly." It should be pointed out that t findings of Prof. Bhattacharya and myself direc



support the previous work of Prof. E. B. Wilson, t distinguished American cytologist.

So far as we are concerned, our material is ve clear and easy to study, and we feel sure that if M Nath examines his slides more carefully, he will fin that Wilson has given the correct interpretation the scorpion spermateleosis.

Herewith we give four photomicrographs of ou material. In Fig. 1 the mitochondrial spheres of th spermatids (*m*), after becoming partially fuse elongate to form a number of leaf-like structures (th mitosome, nebenkern, etc.), shown well at *mx* in Fig. The nucleus at this stage elongates rapidly (N), whi the leaf-like mitochondria further elongate to form club-shaped structure (Figs. 3 and 4) which eventuall becoming more attenuated, forms the tail as claime by Wilson. In Fig. 4 the nucleus, N, is partly out focus, but joins the mitosome at *m*, and passes bac to the axial filament (*f*), which is embraced by th residual protoplasm containing the Golgi bead.

Moreover, if the mitochondria are rejected, as Mr. Nath's letter suggests, one would expect to find evidence for this in the residual protoplasm, as has been done in pulmonate molluscs (Gatenby). If sloughing occurred at all in the spermatids overloaded with mitochondria, it could only apply to the very tail end, and certainly only after the middle piece had been formed directly from mitochondria.

Both Prof. Bhattacharya and I are hoping to demonstrate our material before the Royal Microscopical Society this winter session. We shall be very glad to see Mr. Nath there, and to witness his demonstration of tail formation in scorpion spermateleosis, by any method other than that described by Wilson and Bhattacharya and myself. Our paper on the scorpion spermatogenesis is being published in Prof. Gregoire's Jubilee Number of *La Cellule*.

With reference to Mr. Nath's observations on Miss D. King's letter on the "Oogenesis of Lithobius," I should say that Miss King has carried out her investigation under my supervision, and I have examined many of her slides. I feel sure that her account is the correct one. The scheme of oogenesis in Lithobius, worked out by Miss King, agrees with Hogben's previous researches on insect oogenesis, and broadly with my own work on Saccocirrus (Archiannelida).

Mr. Nath mentions that in "Saccocirrus (Gatenby)" the Golgi bodies undergo fatty degeneration. This is incorrect: what I did write was (*Q.J.M.S.* vol. 66, p. 15) that, "From the method and time of appearance of the fatty yolk, I believe it is formed from the Golgi bodies, but I admit it is impossible to make a trustworthy statement in such unfavourable material." The whole point of my Saccocirrus work was that the yolk is nucleolar in origin.

There is one point mentioned by Mr. Nath which is really of interest and value, provided his observations are correct, and I sincerely hope that they are. In a list of animal groups in which the mitochondria directly form the tail, Prof. Bhattacharya and I mentioned (NATURE, June 14): moths (Meves and Gatenby), cockroaches (Duesberg), Annelids (Gatenby), scorpions (Sokolow, Wilson, Gatenby, and Bhattacharya), mammals (Duesberg, Regaud, Woodger, and Gatenby, etc. etc.), and certain molluscs also (Gatenby, etc.), and now Mr. Nath states that in his centipede the mitochondria directly form the tail. This is good news to me.

In many of Miss King's Da Fano preparations we found argentophile rings on the sperms. We have not yet worked at the spermateleosis, but I am much interested to read that Mr. Nath also finds Golgi bodies on the tails of the spermatozoa of his specimens. The only spermatozoa hitherto positively known to carry Golgi elements are those of Ascaris and Cavia, but there are other more doubtful cases. It will be curious if later work shows that the argentophile rings of the centipede sperms are really Golgi bodies.

Until Mr. Nath has the opportunity of reading Miss King's full paper, which will appear about Christmas in the Proceedings of the Royal Dublin Society, I feel that further comment will not be of advantage to cytology in general. J. BRONTË GATENBY.

Trinity College, Dublin,

Interpretations of Primitive American Decorative Art.

DR. H. O. FORBES in his communication on "Pre-Columbian Representations of the Elephant in America" in NATURE of August 2, p. 174, makes some statements on which I would like to offer comment. In his attempt to discover a basis in the Cephalopoda for the decorative *motifs* under discussion, Dr. Forbes states (p. 176) that "In the argonaut, the two central arms, when all are spread, are often so closely apposed as to appear a single very broad tentacle—a feature very conspicuous in the South Atlantic Bathypolypus." Now "central" arms can either mean the second and third of each side or possibly the first and last of both sides (the dorsal and ventral pairs). In either case Dr. Forbes's statement is inaccurate, so far as I can judge from the examination of numerous specimens and figures of Argonauta. The arms in question are not thus "closely apposed as to appear a single very broad tentacle." The statement seems to be likewise inapplicable in the case of Bathypolypus. This genus was founded in 1921 by Grimpe. It was not defined by him though he designated the type (*Octopus arcticus* Prosch). A definition prepared by myself, after correspondence with Dr. Grimpe, is in the press at the present moment. This genus includes *Octopus arcticus* Prosch, *faeroensis* Russel, *lentus* Verrill (N. Atlantic), and *grimpei* Robson (M.S.), and *valdiviæ* Thiele (S. Atlantic). It is doubtful at present what others should go into it. In any event, the two South Atlantic species have not the characters attributed by Dr. Forbes to the genus.

I may be doing Dr. Forbes an injustice. I may have overlooked in a recent fairly exhaustive search a large number of species having the character described by Dr. Forbes and transferred to Bathypolypus. If that is the case I should be very grateful for information concerning such cases.

With regard to the suggestion made by Dr. Forbes that the Maya and Copan sculptures can be interpreted as figures of highly conventionalised Cephalopods, I feel that the evidence is insufficient to sustain his theory. I admit that the Manabi slab (Dr. Forbes's letter, Fig. 1, p. 174) looks like a conventionalised squid, though I feel that careful examination would very much modify this preliminary impression (for example, if a squid, why *eight* arms? ; ? meaning of the four arms or tufts on the "mantle"; ? *circular* ends of arms). With regard to the Tikal lintel (Fig. 2) I confess that I feel a little less compromising. According to Dr. Forbes the central part of this design is a "specialised" (sic !) "argonaut or octopus" with beak and two glaring eyes, etc. I can only say that, if this is a true interpretation, then the artist has thrown the structure of his model to the winds and relied on the most generalised conception. This is no doubt very often done in highly conventionalised art, but the admission weakens any interpretation that relies on the data of realism, as Dr. Forbes does. The "superciliary ridge" from under which the eyes glare out is, according to Dr. Forbes, "the fleshy upper margin of the mollusc's mouth." In other words, the eyes and mandibles of the supposed Octopus, which are in the living animal on opposite sides of the umbrellar membrane, are not only on the same side of the latter in the Tikal lintel but the eyes are also actually placed inside the labial membrane! The structures assumed by Dr. Forbes to be sucker-bearing arms may conceivably constitute a *motif* based on these structures; but the round circles (*sc.* suckers) turn up in this design in places where it is difficult to assign them to any particular arm, so that they may be merely decorative symbols devoid of any natural basis.

While allowing a vague suggestion of a cephalopod *motif* in Fig. 2, I consider such an interpretation quite devoid of basis in Fig. 3, while in the case of the Copan Stela it is not possible to offer any serious comments, as the photographs are not good enough to enable one to form an opinion. Fig. 5 may suggest a squid, though its apical extremity is curved suspiciously like

an elephant's trunk; while one would have thought that alongside the "trunk" in Figs. 5 and 6 there were represented (in a conventionalised fashion) structures that look like tusks.

In conclusion, I should like to say that Dr. Forbes has certainly rendered a service in giving alternative explanations to some of the *motifs* of primitive American art. I do not agree that any of the figures (except possibly that of the Manabi slab) reveal a *whole* cephalopod, though parts of his Figs. 2 and 7 suggest that the arms may have been employed as incidents in larger designs. I feel, however, that unless we can obtain evidence as to the earlier stages from which this very conventionalised and, I venture to suggest, somewhat debased method of design was evolved, a Proboscidean, a Molluscan, or even a Cœlenterate interpretation will be equally plausible.

On the Mercury Line λ2270 A.

IT is a remarkable fact that of the three transitions of an electron in a mercury atom represented by $1S-2p_1$, $1S-2p_2$ and $1S-2p_3$, we see optically only $1S-2p_2$ (λ2536), while the other two, namely, $1S-2p_1$ (λ2270) and $1S-2p_3$ (λ2655), have not been observed at all except by the indirect method of measuring the ionisation by impacts of electrons on atoms by Franck and Einsporn (*Zeit. f. Physik*, ii. p. 18, 1920).

In 1922, at the suggestion of Prof. N. Bohr, one of us, in conjunction with Prof. H. M. Hansen and Dr. S. Werner (Kgl. Danske Videnskab. Selskab. Math.-fys. Medd. v. 3, 1923), tried to find how to make possible the transitions from these two meta-stable states $2p_1$ and $2p_3$ to the normal state $1S$.

As a result, we found that the line λ2270 is excited in a Geissler tube when a condensed discharge is passed, whereas the line λ2655 was not detected at all.

In the present experiment, the account of which will be published later in detail, we tried to get the line λ2270, not in the spark spectrum but in the arc spectrum of mercury.

We found that the arrangement used by Messrs. Metcalfe and Venkatesachar (Proc. Roy. Soc. A, 100, p. 149, 1921; A, 105, p. 520, 1924) for the study of the absorption of mercury lines produces the line λ2270 with considerable intensity. Instead of using the long tube filled with mercury vapour as the source of absorption, we employed it for emission, and by passing a current from 2 to 3 amperes through the long tube, which we might call "a branched arc," we found that the intensity of the line λ2270 could be raised so as to come between $m=8$ and $m=9$ in the diffuse series $\nu=2p_2-md_2$. In other words, the line λ2270 appears stronger than λ2303 ($m=9$), but fainter than λ2323 ($m=8$).

Using the largest size of quartz spectrograph made by Hilger (Littrow type), and photographing in juxtaposition the line λ2270, first as excited in the above method, and second as excited in a condensed discharge, we found that the latter method of excitation gives a shift of about 0·1 A to the red side, with a faint companion line on the red side at a distance of about 0·2 A.

Similar shifts were observed for the line λ2345 ($\nu=2p_3-5s$) in the same sense, but in the opposite sense for the line λ2564 ($\nu=2p_2-4S$). The shifts are not due to the manner of projecting the image on the slit, since there are many lines which show perfect coincidence; neither does it seem likely that the shifts are due to the Doppler effect, as they remain the same when we change the polarity of the condens discharge, which was fairly well rectified.

No trace of the line λ2655 ($\nu=1S-2p_3$) w observed.

A Rotational "Fatigue" Effect of the Electric Discharge.

IN some recent experiments on the volt-ampe characteristics of low-tension discharge tubes, I utilise an "Osglim" lamp of the "beehive" variety, sealir it on to an apparatus so that air at different pressur could be introduced. (The lamp consists of an iron dis anode and a spiral cathode of thick iron wire, woun above the anode.)

It was observable at certain pressures that, whe the discharge was continuous, but failed to cov completely the cathode, the discharge shifted fro one part to the other of the cathode surface, ofte undergoing a regular cycle. At other times th motion was along the wire of the spiral, slowly bac wards and forwards through a rotation of up to 120 and even more. The rotation continued over lon periods of time in a most interesting manner.

The phenomenon is apparently an electrod "fatigue" effect. When one portion of the surfac has been serving as cathode for some time, it become "fatigued," and the value of the cathode fall potential rises; it then becomes easier for the dis charge to pass over at an adjacent portion of th cathode, and consequently the discharge rotate slowly.

That the rotation is accompanied by a correspond ing fluctuation of the voltage drop across the tub is evident from the fact that the reading of the volt meter, across the tube, rises and falls at a simila rate (there is of course a lag), and to a lesser degre variation of the current is observable.

Secretary to the International Commission on Zoological Nomenclature.

Hygienic Laboratory, Washington, D.C.

Chemistry and the State.[1]

By Sir ROBERT ROBERTSON, K.B.E., F.R.S.

THE appeal of the State to chemistry has developed through the gradual recognition of the need for the application of that science to matters relating to the preservation, its currency, its financial support, its health, its food supply, its industries, and finally to academic science. In the course of this development in Great Britain, advantage has been taken, if sometimes tardily, of the general advance in chemical knowledge, and frequent recourse has been had to the advice of well-known chemists of the day, and collectively of the Royal Society; thus for various purposes the following chemists, as officials or consultants, have in the past afforded assistance in the solution of specific problems referred to them, or by taking part in Commissions: Boyle, Newton, Davy, Faraday, Daniell, Graham, Hofmann, Redwood, Abel, Roberts-Austen, Mercy, Dupré, Playfair, Frankland, Ramsay, and Dewar. It has happened in several instances that as a result of these Commissions and references to chemists, some definite chemical activity of the State has emerged. The following summary reviews the State's chemical activities before, during, and after the War.

BEFORE THE WAR.

Defence.—For the defence of the State, establishments for the production of explosives were early maintained, and when this ultimately took the form of a chemical manufacture, the Government factory took the lead in devising efficient processes, while from the various State research establishments has issued during the last fifty years an important body of original contributions to the theory of explosives and to the knowledge of their properties.

Metallurgy.—The metallurgical progress of the country has always been a concern of the State by reason of its application to defence by land and sea, and close touch has been maintained with successive developments in the manufacture and use of cast iron, wrought iron, steel, and non-ferrous alloys. While the main advances in process have been made in the great iron and steel works, material contributions to knowledge in this sphere have been made by chemists in the Government service.

Revenue.—For the revenue of the State, imposts were applied in early times, but with great uncertainty, until the charge was put on a scientific basis. Very accurate tables for the strength of alcohol were worked out under the supervision of the Royal Society at the end of the eighteenth century, to be superseded by revised ones issued only a few years ago, when, in addition, new tables were issued also by the Government Laboratory, for determining the gravity of worts before fermentation. The question of rendering alcohol unpotable, but still useful for industrial purposes, has occupied much attention. It was on account of the necessity for safeguarding the revenue that the Government Laboratory was primarily erected, although it now performs chemical work for all State Departments of Great Britain.

Health.—The three main steps with regard to public health and sanitation in this period were the forcing of these questions into prominence by Playfair, with the consequent Commissions and legislation leading to the formation of the Local Government Board and its successor, the Ministry of Health, which has many varied activities in preserving purity of air and water and protecting the workman in dangerous trades; secondly, the determination of standards for a safe water supply by the pioneering work of Frankland; and, thirdly, the appointment of public analysts by the local authorities, with the Government Laboratory as referee, for safeguarding the supply of food.

Agriculture.—Science was being applied to agriculture about the end of the eighteenth century, and at the beginning of the next, Davy did pioneering chemical work for the Board of Agriculture. Private endeavour is responsible for the next development, State action being limited to the prevention of fraud in the sale of fertilisers and feeding-stuffs. In 1909, however, the annual allocation of a sum of money to the Development Commission for the advancement of agriculture stimulated research in a large number of institutions engaged in the scientific study of problems in which chemistry plays an important part.

Other Activities.—In addition to the chemical work referred to above, there is a variety of subjects connected with State Departments to which chemists have contributed, such as the composition of the sea, and the composition and physical chemistry of rocks and building-stone. At the Government Laboratory a large number of investigations have been conducted on matters directly referred from Government Departments.

DURING THE WAR.

In all the activities described, the War requisitioned the work of the chemist, but, naturally, predominantly to meet the demands of active warfare.

Defence.—The attention that had been bestowed on the subject of propellants enabled expansion to take place with no important alteration in the technique of their manufacture, to which was adapted a new type of cordite, ultimately made on the largest scale, without using an imported solvent. For high explosives Great Britain was in much worse case, as these had not been made by Government, and were manufactured only in small quantity. Their study at Woolwich led to a rapid evolution of new processes, substances, and methods of use. Thus a method was worked out for the manufacture of trinitrotoluene, and to save this substance a new high explosive, amatol, was devised. This explosive, consisting of ammonium nitrate and trinitrotoluene, passed exhaustive trials and was ultimately produced at the rate of 4000 tons a week. The production of the ammonium nitrate for the mixture was in itself a stupendous undertaking, and the methods of filling the explosive into shell and other munitions gave rise to much ingenuity. In the Research Department, Woolwich, the number of qualified chemists engaged

[1] From the presidential address to Section B (Chemistry) of the British Association, delivered at Toronto on August 7.

in the study of explosives in all their aspects ultimately exceeded a hundred, while for manufacture and inspection more than a thousand were employed. The ideal set before himself by Lord Moulton in 1914, to produce nothing less than the maximum of explosives of which Great Britain was capable, was realised, and they assumed a quality and character that caused them to be copied by our Allies, and proved themselves more trustworthy than those of the enemy.

Starting unprepared, and without the advantage of a well-developed fine chemical industry, Great Britain was able ultimately to make a reply in the field of chemical warfare that was rapidly becoming more and more effective; at the same time, by study and often self-sacrificing experiment, protecting the soldier by the development of very efficient respirators. In this connexion and in that of explosives, nearly every professor of chemistry in the country, and many from beyond the sea, were engaged.

Metallurgy.—The enormous demand for metals for munitions and countless other war requirements led to an unprecedented concentration of the metallurgical industries on the needs of the State, and to an equal concentration of metallurgical science on investigation devoted to improvement in quality of materials for new and special war purposes. The work of the Aircraft Production Department, aided by many metallurgists and engineers, on alloy steels; of the National Physical Laboratory on aluminium alloys; and of the Metallurgical Branch of the Research Department, Woolwich, on the heat-treatment of heavy forgings and on the drawing of brass, is typical of the successful effort made in every quarter. The knowledge thus gained was disseminated in the form of specifications, instructions, and reports, and has had a great and permanent effect on manufacture.

Health.—A committee of the Royal Society had been studying food values, and was able to afford the Food Controller, when he took office, valuable data bearing on the rationing of food. The committee had dealt with subjects which shortly became of much importance, such as a better recovery of flour in milling wheat. The chemical examination of the food for the Army during the War, carried out by the Government Laboratory, employed a large staff of chemists. For the supply of many fine chemical substitutes used in medicine and surgery, formerly imported from abroad, such provisional arrangements had to be made as the organisation of a large number of university laboratories on a semi-manufacturing basis.

Agriculture.—Effects on agriculture during the War were shortage of the usual feeding-stuffs for cattle and of fertilisers. The chemists stationed at Rothamsted gave special attention to the shortage of manures and prepared instructions for the guidance of farmers; and several sources of supply of potash were exploited, including kelp, felspar, and the flue-dust of furnaces. As sulphuric acid was required for explosive work, fine grinding of phosphates and basic slag was adopted and found to be more efficient than was expected. Shortage also directed the attention of chemists to the use of little known food-stuffs, especially for cattle, and the information gained as to their feeding value was important.

Other Activities.—In many other activities in connexion with the War, chemists were directly involved, such as in affording advice on the conservation of materials, on the numerous questions arising from the operations of the War Trade Department, on the restriction of imports and exports, and on matters of contraband.

After the War.

The magnitude of the chemical effort, it can be claimed, was a factor in winning the War which must be reckoned as of importance only second to that of the bravery of our forces in the field. But it has left a lasting mark, and given to chemistry a value which were it not for the rapidity with which the achievements of science are forgotten, ought to keep before the public its connexion with almost every phase of activity.

Defence.—To take our subjects in the same order we may consider some of the effects of the energy spent on the production of munitions. The intensive study of explosives and of other chemical substances used in the War has led to a more complete knowledge of their chemistry, their physical and explosive properties, and has advanced chemical theory. These advantages are not of military importance only, but are reflected also in the production of trade explosives. The collected records of the Department of Explosive Supply afford examples of treatment of many problems of interest to the general chemical technologist, and not only to the explosives expert.

A further benefit was reaped by chemists in every position, from the professor to the youngest graduate coming into direct contact with manufacturing methods and thus gaining insight into the applications of their science. While it is true that the opportunity came to few of these to take part in the design of plant and primary choice of process, nevertheless the experience was a novel one, as it led them into the field of technology, and cannot fail to have widened their outlook. It became apparent that there was a shortage of a type of chemist which had been developed in Germany, skilled in the transference of the chemical process from the laboratory to the works scale in the largest enterprises. A chemist of this type is one who, besides having a sound knowledge of chemistry and physics, has had experience in the materials of construction used on the large scale, and in the operation of the usual types of plant for carrying out the operations of chemical manufacture, and is capable of working out flow-sheets illustrating the process, and operating plant with every regard to economy. The need for instruction in such subjects had been borne in on men like the late Lord Moulton, and as a direct result of the war-time experience of our deficiencies in this direction has arisen the movement for creating chairs of chemical engineering in some of our universities. It is to be expected that from these schools, especially where the instruction is superimposed upon a full graduate course, will come men who will lead the way in the application of academic science to industry.

Metallurgy.—While the interest of metallurgical science in war material has fortunately fallen to a peace-time level, State participation in the support of scientific research remains far greater than before the

far. In metallurgy it is exercised through the partment of Scientific and Industrial Research, with organisations of the National Physical Laboratory d the Industrial Research Associations, as, for ample, those dealing with the non-ferrous metals and th cast-iron. The State also continues to maintain icient research departments for the Fighting Services, t it is significant that the largest of these is under-king industrial metallurgical research on a con-derable scale, for the benefit of the brass and other dustries. State support and encouragement are doubtedly powerful factors in the rapid progress w taking place in every branch of metallurgical ience in Great Britain, and there is scarcely any lated industry which can fail to benefit.

Revenue.—Since the War the principal matters fecting the revenue are the higher duties, which have ndered necessary a further denaturation of alcohol. nproved facilities have been granted for the use of cohol for scientific purposes and in industry; regula-ons have been formulated for the use of power cohol, and duties have been established on imported e chemicals and synthetic dyestuffs.

Health.—The food shortage during the War directed tention to the nature and quantity of our food pplies, and led to further investigations being under-ken by the Department of Scientific and Industrial esearch on food preservation and storage. Activity also shown by the appointment of committees which re working on the subject of preservatives and colour-ng matter in food, and on the pollution of rivers by ewage and trade effluents. A great field is open in he co-operation of chemistry with medicine in the iscovery of substances suitable for the treatment f the numerous diseases now traced to parasites in he blood.

Agriculture.—So far as fertilisers are concerned, the ack of a supply of fixed nitrogen from the air which btained throughout the War has now been rectified, nd Great Britain for the first time is no longer ex-eptional among the nations by neglecting to provide tself with synthetic ammonia for agriculture and for unitions. Such war-time expedients as the use of itre-cake instead of sulphuric acid for making mmonium sulphate and superphosphate, and the ecovery of potash from flue-dust, have not survived, ut there has been a gain in the further development f "synthetic farmyard manure" and the increased se of basic slag. The present activity in research in gricultural chemistry of a fundamental character is eading to a better understanding of problems of the oil and of plant and animal nutrition, and cannot fail o be of ultimate benefit to farming.

Organised Applied Research and Assisted General Research.—Established during the War as a result of an appreciation of the contrast between the successful application of scientific method to military purposes and the want of such application to many of our manufactures, the Department of Scientific and Industrial Research has extended over a wide field. Its main activities are in the directions of State encouragement to industry to apply chemistry to its problems, of State investigation of vital problems beyond the sphere of private enterprise, and of assist-ance to workers in the purely academic field. In all these spheres activity is shown by the contributions to knowledge already forthcoming.

Personnel.

In the expansion that has occurred in the chemical sections of State Departments since the War, it is interesting to note the increase in the number of chemists that are employed. So far as can be gathered, the number of chemists working in departments maintained wholly by the State is 375 for the present year, compared with 150 in 1912, while in establishments to which the State affords partial support, such as those under the Development Commission and the Research Associations, the corresponding numbers are 150 and 50. In addition, grants are made to 145 research students and to 11 independent research workers, involving a yearly sum of about 50,000*l.*

Development of Chemistry in the Modern State.

From the foregoing account of the connexion of the Departments of State in the United Kingdom with chemistry, it is possible to trace a gradual development and ultimately a change in attitude, in passing through the stages of compulsion, expediency, and assistance.

From motives of security the State was compelled to give heed to chemical matters involved in its defence, such as those which appertained to munitions of war, including metals used in their manufacture; it was constrained to uphold the standard of its currency; and it was obliged to secure a revenue. As a consequence, the first chemical departments were set up in connexion with these activities, and from them have emanated notable additions to chemical knowledge, improvements in methods of manufacture, and specifications for Government requirements that have led to improved material becoming available for civilian use. Although mostly conducted with inadequate staff, the study of these questions, it can be claimed, proved of national advantage when the time of need arose.

In the next stage, the public conscience having been awakened by the pioneering work of Playfair, it appeared expedient to safeguard health by attention to sanitation, and, as the quality of food was unsatisfactory, to set up a chemical control. Although a start was made by Davy, a member of the Board of Agriculture of the day, progress in this subject passed to private enterprise, and a century elapsed before direct assistance was afforded to this important matter. Out of these activities come our present system of supervision over the purity of air, water and food, and also the recent progress made in the application of chemistry and physics to problems of the soil.

The last and more recent stage is in the nature of a recognition that the State is under an obligation to assist science, and in this case the science of chemistry, on which so many important industries are based. The War brought home the danger that, although the record of Great Britain as regards discovery in pure science was unrivalled, its systematic application was too often left to other countries, with the result of lamentable shortages during the War and the risk of many industries being ineffective in peace. A measure of government intervention and action appeared

requisite, and research became the business of a government department. Outside of the great firms which maintain progressive chemical staffs, the firms in numerous industries have been encouraged and assisted to co-operate in the betterment of their manufactures by the application of the methods of science, and from these associations and the organisations dealing with national problems begins to flow a stream of communications indicative of useful work accomplished. Nor is the foundation of it all neglected, for encouragement is given to workers in the academic field to follow out their ideas, whithersoever they may lead them, in accordance with the truth that "research in applied science might lead to reforms, but research in pure science leads to revolutions."

It is important to be able to record an advance in securing an interchange of information among government departments, and between their work and that of the universities, a matter which before the War was unsatisfactory, as it was mainly personal and sporadic. It is also a hopeful sign that, although the knowledge and appreciation of the methods and capabilities of science are still generally wanting, there have been signs of late years that these matters are coming to engage the attention of those who guide the policy of the State.

Centenary of the Franklin Institute.

ON March 30, 1824, the Governor of the State of Pennsylvania signed an Act incorporating the Franklin Institute for the Promotion of the Mechanic Arts. The centenary of its foundation will be observed in Philadelphia on September 17, 18, and 19, by celebrations reminiscent of the rise, growth, and continuity of purpose of a remarkable institution, now, after many inevitable vicissitudes, rooted deeply in the national life of the United States, at the same time commanding the allegiance of men of science in most other countries. Accordingly, delegates representing several of the universities of Great Britain, as well as scientific societies, will join those from Canada, France, Holland, and Germany in united expression of congratulation. To have wrested "secrets of excellent use" from Nature marks and cements the common bond.

When we direct our minds back to the Institute's initial year, 1824, it serves us to recall that here, in England, we had Sir Humphry Davy—at the height of his fame—installed as president of the Royal Society, whilst round about that period many special scientific organisations were springing into being. Among such were the Horticultural Society (1804), Geological Society (1807), Institution of Civil Engineers (1818), the Royal Geographical Society (1830) and the British Association (1831).

The Franklin Institute was established to meet the need for an institution similar to that founded in London in 1799 (the Royal Institution) by Benjamin Thompson, Count Rumford. The founders had before them, also, the history and objects of the Anderson College of Glasgow, where Dr. George Birkbeck had lectured on mechanics and applied science with inspiring zeal and successful issue. The initial tentative effort was due to two Philadelphians, Samuel V. Merrick and William H. Keating, the latter then chosen by the University of Pennsylvania to occupy a new Chair of Chemistry in its Application to Agriculture and the Mechanic Arts. They discussed a project—one of them, by the way, had been told he was wasting his time—but they were bent upon going forward. They called in two others as colleagues, and the four—all young men—using the Philadelphia Directory, selected from it the names of some 1500 citizens, inviting them by circular letter to attend a meeting on the evening of February 5, 1824, to discover and talk over plans. The meeting was a success, not a little to the surprise of its conveners, approbation of the purpose in view, namely, that of assisting the knowledge of physical science and its diffusion in the arts and sciences, being expressed freely. Later, an election of officers took place, and the promoters chose a name for their offspring. Certainly none could have been more fitting than that of "Franklin Institute," both for immediate testimony and posterity's keeping. There seems to have been no dissension. The glamour of the great "printer-philosopher" was with them in the city where he had worked, and hence homage was rendered. The original scheme prospering, in twelve months' time the corner-stone of a marble-fronted building, destined as a home, was laid (we are told "in ancient and Masonic form by the Grand Lodge of Philadelphia, in the presence of the Society") on June 8, 1825, and completed in 1826. Upon the first floor (to-day) are located the lecture room, laboratories, and offices. The second floor is occupied by the library, whilst the third is devoted to the Museum of Models and Historical Apparatus.

Membership of the Institute is open to men and women, without regard to distinction of race, nationality, or religion, the only requirements for admission being good character and interest in its work. The artisan and the professor meet within its walls upon an equal footing, and it is to this happy blending of "Science with Practice" that the particular usefulness, past and present, of the Institute must be ascribed. General meetings are held once each month, except during the summer. At these, inventions and discoveries, important engineering projects and notable achievements in all fields of scientific progress, are presented, exhibited, or discussed. Many epoch-making inventions have been shown in their experimental stages at these meetings—for example, the phonograph, electric arc, the typewriter, liquid air apparatus, and telegraphy improvement devices. The average membership for the period 1912–1922 was 1380, and in view of the greater interest now manifested in the Institute's work, special efforts are to be made towards an enlargement of its roll.

Three permanent features of the Institute's activities are the maintenance of a reference library, the holding of exhibitions, and the publication of a Journal for the diffusion of knowledge on all subjects connected with science and the useful arts. All three formed part of the original plan of the founders, and the efflux of time has added materially to their importance. We gather from a recent report referring to the library that it is,

its class, second to none in the United States, em-cing the publications of the principal scientific and hnical societies of the world. An extensive collec-n of patent literature has been brought together lispensable to inventors and manufacturers. It is rthy of mention that in 1922 the library received unique and valuable collection of books and pam-lets on windmills, inclusive of treatises on the subject nted in German and Dutch in the seventeenth and hteenth centuries, and a book of 400 views of wind-lls in all parts of the world. As a means of fostering e mechanic arts, the holding of exhibitions was very rly encouraged, and for many years kept in view. notable one was the Electrical Exhibition of 1884, ld under the direction of the Institute and by Act Congress made international in character.

The Journal of the Institute in its present form is an tavo of about 150 pages, published monthly, and it nsists in large part of reports of lectures delivered fore the Institute and its sections, together with lected original communications from specialists. ention may be made of a paper by Dr. F. W. Aston, "Atomic Weights and Isotopes," being a summary a series of lectures delivered before the Institute in 22. A series of lectures was also given in 1923 by r J. J. Thomson, on "The Electron in Chemistry." ere it is convenient to record that the Institute now blishes annually a "Year Book," which we may y is one of the most concise and distinctive issues the kind that we have seen.

Various honorary awards of medals and premiums e made by the Institute, some of which are of old anding, and highly valued, such as, for example, the lliott-Cresson, Potts, and Longstreth medals. The ost recent foundation is the Franklin gold medal (with iploma), instituted in 1914, and allotted annually to ose workers in physical science or technology, without gard to country, whose efforts, in the view of the nstitute, acting through its Committee on Science and he Arts, have done most to advance a knowledge of hysical science and its applications. The latest ecipient of this gift was Sir Ernest Rutherford.

Under new rules, adapted to modern requirements, he Institute conducts investigations, through its Committee on Science and the Arts, on the soundness and practicability of inventions, discoveries, and improvements in physical processes or devices, submitted to it. During the past twenty-five years nearly 1000 applications have received adjudication.

In 1921 the Institute received a bequest from Henry W. Bartol, a life member, of 1,208,468 dollars for research. Agreeably therewith a "Bartol Research Foundation" was established for the purpose of conducting researches relating to fundamental problems in physical science, particularly those in the field of electricity, and for the investigation of specific problems of a scientific nature which may arise in the industries. An arrangement was made to build a laboratory wherein to engage in these objects, but unfortunately up to the present nothing has reached fulfilment, owing to the high cost of building construction. It is a trust which we may be sure will eventually become operative.

The principal events of the Centenary programme comprise, on the first day, an assembly at the Franklin Institute, and an academic procession to the Walnut Street Theatre, where the Mayor of Philadelphia will deliver an address of welcome, and addresses will be given by Dr. W. C. L. Eglin, president of the Institute, and Prof. Elihu Thomson, honorary chairman of the Centenary Celebration Committee. On September 18 the chief fixture is a lecture on "The Natural and Artificial Disintegration of Elements," by Sir Ernest Rutherford. The morning of September 19 will be taken up by the unveiling of a tablet in connexion with the Bartol Research Foundation. Addresses will afterwards be given by Dr. Arthur D. Little, of Cambridge, Mass., on "The Fifth Estate," and by Prof. Jacobus, advisory engineer, the Babcock and Wilcox Co., New York City, on "Stimulation of Research and Invention." Garden parties, and fraternal hospitality in the shape of banquets to the delegates and guests, have all been provided for in unstinted fashion. A list of speakers at the sectional meetings has been drawn up. These include Sir Charles Parsons, Sir William Bragg, Prof. E. G. Coker, Prof. A. A. Michelson, Prof. Zeeman, and Prof. F. Haber.

NATURE proffers its heartiest congratulations to the Franklin Institute on the occasion of the Centenary, and its earnest hopes for future development and prosperity. T. E. J.

Current Topics and Events.

THE three hundredth anniversary of the publication of Francis Bacon's famous "De Dignitate et Augmentis Scientiarum" was fittingly celebrated at the seventy-eighth meeting of the American Association for the Advancement of Science at Cincinnati by a symposium of five papers, which have recently appeared in *Science*. Special interest attaches to the first of these by Prof. Mark H. Liddell, of Purdue University, outlining Bacon's scheme for a College of Research. His plea for the proper organisation of research is preceded by an attack on the neglect of science in the university of his day. "If any man thinks pure science an idle pursuit he fails to realise that from thence is all applied science supplied." Bacon accuses the college professor of his day of lacking in virility, and attributes this in part to the smallness and meanness of his emoluments. He also accuses the universities of their failure to produce facilities for research "in the way of laboratories, botanical gardens and other instrumentalities of investigation," and insists that "research is the intelligence department of organised knowledge," and hence must be properly financed. So Bacon comes to his own programme for the regeneration of learning by research, along two broad lines: one to provide the scientific method for the *magna instauratio*, the other the material and personnel to make it effective. The former of these he achieved in 1620 with the publication of the "Novum Organum." The second object, the provision of the College of Research (Bacon called it a College of Inventors), was never realised, but his own memorandum,

originally drafted in 1608, clearly outlines his intentions. Bacon contemplated a building equipped with libraries, laboratories, furnaces, vaults, and workshops, together with a hall of fame for statues of the great men of science, past, present, and future. There were to be rules for the conduct of studies and research, and money allowances for travelling expenses and for apparatus. There was also included a scheme for the recording of results in cipher until the time for publication was deemed appropriate. Finally, the scheme provided not only for the due rewarding of valuable research, but also for the removal of members whose work was fruitless.

ORNITHOLOGISTS have recently been hearing a good deal of the International Museum of Comparative Oology at Santa Barbara, California. We have now before us the first number of the Journal of this Museum, edited by the director, W. L. Dawson, and entitled *The Comparative Oologist*. Throughout, the claim is made that oology is an independent science of considerable importance—once indeed we are told that "Oology is the science of one half of the biologic process"; but the Journal itself enables us to see how much weight is to be attached to these claims. We will content ourselves with one passage, in which the editor informs us that the shell of a bird's egg has been formed in the ovary, "that innermost sanctuary of life"! and therefore enables us (how is not stated) to penetrate into the mysteries of "the reproductive stream itself." Numerous other quotations could be made to show that Mr. Dawson, while admirably qualified to write of generalities in a high-faluting style, appears to be unfamiliar with elementary facts concerning his special subject-matter. We wonder what men like Dr. R. Ridgway, Dr. Shufeldt, Mr. Oberholsen, or the Rev. F. Jourdain will feel when they see themselves associated with the highly original avian anatomy and physiology of the sort we have quoted. We may also quote from the rules: "Any person of scientific integrity, having attained the age of 18, who is interested in the pursuit of oology as a science *or in the collecting of birds' eggs* (italics ours) may become a 'Scientific Member' of the Museum." That is what many had supposed: now we know it. But the Museum cannot have it both ways. It can be a centre for egg-collectors, patrons of what is an amusing and interesting sport if not carried (as unfortunately sometimes happens) to the pitch of mania. Or it can be an institution for the scientific study of egg-shells, from which we may doubtless expect some, though not very much or very valuable, new knowledge. But it must not think that it can use science as a cloak for mere collecting; and that is precisely what, with its present rules and organisation, it appears to be trying to do.

THE subject of chemical apparatus and plant production generally received special consideration in the recent address of the retiring chairman (Mr. L. M. G. Fraser) of the Chemical Plant Manufacturers' Association. The improvements in the construction of plant have been along well-defined lines, the aim being to produce a better article at a lower working cost and with greater safety. Examples were given indicating lines of progress, and reference was made to (1) the more economic output of grinding machines, (2) the simplification of emulsion formation, (3) the increased usefulness of filter plant and the development of the stream line filter, (4) the distillation of special liquids with less risk and greater economy and the more efficient fractionation in still columns, (5) improved mechanical crystallisers and mixers, (6) the more thorough understanding of furnaces, and (7) the control of temperature. The better utilisation of metals and alloys and the more intimate knowledge of the action of heat on substances are regarded as factors which have helped progress. The separation of ashes from coke and unburnt coal by means of electromagnetic separators is now being carried out on a commercial scale. Recent developments in electrolytic cells were also noted, and the need for further investigation on the electrolysis of certain inorganic substances indicated. Mr. Fraser is hopeful that, with experience from similar work in other directions, plant could be properly designed to meet new needs. Many general questions bearing on plant construction were touched upon, such as the power factor in the movement of bulk materials, the study of the thermal efficiency of fuels and the interchange of heat, the general freedom from breakdown of machinery and the automatic control of operation. Improvements so far achieved have enabled many difficulties to be overcome, and future plans can be laid with greater confidence.

TWO series of coloured postcards have recently been issued by the British Museum (Natural History), one depicting the migrant bird visitors of spring, the other those of winter. A separate card is devoted to each species, and in many instances, to an excellent "close-up" view of the bird in its normal surroundings, there is added a more distant view which indicates with great success the features that catch the eye "in the field." The colouring is very faithful to life, and the artistic effect of each card delightful. Each series is offered in sets of five cards for 1s., the cards being numbered in the order in which the birds usually arrive in Great Britain. Thus the first set in the spring series contains wheatear, ring-ouzel, chiffchaff, sand martin, and swallow; and that in the winter series, snow-bunting, redwing, brambling, fieldfare, and hooded crow. Accompanying each set is a printed leaflet in which the breeding and migration habits of each species are set out. In addition to giving much pleasure to all bird-lovers, these cards should prove of great value to teachers in supplementing lessons in Nature study, especially in urban schools and in those which have not the good fortune to possess a natural history museum.

THE number of new periodicals dealing with various aspects of natural science which have been started in Japan in the last few years, is clear evidence of the attention now being given in that country to the investigation of its own natural resources; for most of the journals contain papers dealing with products occurring in Japan or which are being imported into

pan for use. One of the most interesting of these urnals is *Acta phyto-chimica*, now in its second year, hich is published by the Iwata Institute of Plant iochemistry at Tokyo, and edited by Prof. Shibata. t it have been published already a number of im- rtant papers, including those of Asahina and Fujita n anemonin, and a detailed résumé by Asahina on s work on *Evodia rutæcarpa*, which has resulted in he isolation of two new alkaloids, evodiamine and itæcarpine. The structures of these bases have een determined, and shown to be related to those of armine and harmaline, familiar to British chemists rough the work of Perkin and Robinson. No less teresting is the series of papers by Shibata and his llaborators on natural flavone colouring matters. n the current number of the journal (volume ii. o. 1), Prof. Asahina and several of his students have n important paper on the ketone of the essential oil f *Elsholtzia cristata*, Willd., which is shown to be a aran derivative, and is only the second substance of his type thus far found among the thousands of nown components of essential oils, the other being emmler's carlina oxide.

A REPORT of the administration of the Meteoro- gical Department of the Government of India in 923–24, by Sir Gilbert T. Walker, Director-General of Observatories, now retired, has recently been issued. Reference is made to retrenchment of expenditure nd to its interference with effective weather warning. The main curtailment of expenditure was effected in elegraphic charges. The issue of the Calcutta, Bombay, and Madras reports was restricted to periods of 10½, 6, and 9 months respectively, and the number of stations reporting was greatly curtailed. Four cyclonic storms were formed in the Bay and one in the Arabian Sea. In May, a severe cyclone was experienced in the Bay, in which the S.S. *Okara* was lost. The loss of this vessel has led to certain changes in the method of broadcasting important weather information, more frequent weather warnings being issued. In connexion with the upper air work, which centres round the Agra Observatory, out of 36 "instru- ment balloons" sent off during the year, there were 21 recovered. Pilot balloon work was started at Bombay and Peshawar. An extension of meteoro- graph flights is contemplated so as to obtain observa- tions to heights of 12 miles or more, and to participate in the important work undertaken in other countries. Radio weather messages are received from ships and greatly supplement the coast observations in the warning of cyclones. For the "Rainfall of India," observations are received from nearly 4000 stations. Seismological observations are recorded at several places in India and are forwarded to the Seismological Committee of the British Association.

THE *Marine Observer* for September, published by the Meteorological Office of the Air Ministry, has recently been received. It is prepared under the supervision of Captain L. A. Brooke Smith, the Marine Superintendent. The publication is essentially a vehicle for supplying to seamen valuable meteoro- logical data of interest for voyages in all navigable seas; numerous incidents are given from the meteoro- logical logs kept for the Office, and mariners are in- vited to contribute information of interest if not regular observers. The current number contains an article on "The Origin of Tropical Revolving Storms" by Capt. D. Brunt, Superintendent of the Army Meteorological Services. A large amount of wireless weather information is given, a special chapter in the issue for each month dealing with a different branch of meteorological information; the September number deals with "wind and set and drift of current." Specimen charts show currents and winds experienced in home waters, cyclone tracks are given for various oceans, a map shows recent ice in the North Atlantic, and notices are given of recent derelicts and floating wreckage. The August number contained a discus- sion on the "Hong Kong Typhoon, Aug. 18, 1923," by Commander J. Hennessy, the Nautical Senior Professional Assistant; also an article on fog by Mr. H. Keeton. A list of contents would be a useful addition to future issues.

THE first conference of Special Libraries and Information Bureaux was held on September 5-8 at High Leigh, Hoddesdon, Herts. The objects of the conference were outlined at the opening session by Dr. R. S. Hutton, director of the Non-Ferrous Metals Research Association, and Mr. J. G. Pearce, director of the Cast Iron Research Association. It has long been felt that many diverse agencies concerned with the treatment of information have problems in common, and need an opportunity to establish mutual co-operation and assistance, and to determine their relationship to the press, and to the great municipal and national libraries and other institutions. The conference, which was highly successful, provided abundant evidence of the interest in this field of work, and in order to ensure continuity of interest, without forming another association, a standing committee of the conference was appointed with power to consider matters in the interests of those engaged in directing or operating Special Libraries, and to convene a further conference at some future date. This committee is representative of a wide range of institutions, and has already held its first meeting. The most striking feature of the con- ference was the keenness displayed by a large number of highly diversified interests, including scientific, technical, industrial, wholesale and retail commerce, railways, political, agricultural, governmental, univer- sities, press, medical, sociological and banking. This diversity served to emphasise the common interest of all these agencies in receiving, treating and distributing documentary material.

THE thirty-fifth annual general meeting of the Institution of Mining Engineers will be held at the Conference Halls of the British Empire Exhibition on Thursday and Friday, October 2 and 3. Sir John Cadman will relinquish his third term of office as president on October 2, when he will be succeeded by Dr. J. S. Haldane, Director of the Mining Research Laboratory and honorary professor in the University of Birmingham.

M. MENGÈS, whose recent book was noticed briefly in NATURE of July 19, p. 85, writes to suggest that we misinterpreted him. In reply we would explain that the phrase "proposes in some measure to revert to the older 'classical' conceptions" was not intended to throw any doubt on the novelty of his ideas. It was only intended to indicate that his theory approximates more nearly to classical than to relativity theories.

AT the opening session of the annual autumn meeting of the Institute of Metals, held at the Institution of Mechanical Engineers, London, on Tuesday, September 9, Prof. T. Turner referred in his presidential address to the growing needs of the Institute in view of the steadily increasing membership, the growth of the library, and the greater use by members of the facilities which are provided. Additional funds are required if the work is to be maintained and extended; and the alternative to a further increase in the annual subscription is an endowment, the proceeds of which would be available for providing the necessary additional accommodation and assistance. Prof. Turner was able to announce a gift of 1000*l.* towards such an endowment. This donation is the largest single gift which the Institute has received, and the Council will shortly take into consideration the question as to how far, and in what manner, it may be made the basis of a larger scheme.

Two junior assistants are required by the Researc Department, Woolwich, for analytical work in co nexion with Internal Ballistics problems. Candidat must possess first-class honours in mathematic Written applications, with copies of testimonials, mu be sent to the Chief Superintendent, Researc Department, Woolwich, S.E.

WE have received from Messrs. Boots their list special research chemicals. We note that the numb of these has increased considerably, and that a gre majority of the compounds are manufactured purified in Messrs. Boots' own laboratories in Nottin ham. As manufacturers and distributors of fin chemicals, Messrs. Boots are in a position to supply, i a state of considerable purity, many of the inte mediates and raw materials which are of interest t workers engaged in chemical research.

Two useful catalogues of second-hand book offered for sale by Messrs. Bowes and Bowes, Trinit Street, Cambridge, have reached us. One (No. 422) i of a miscellaneous character dealing with works biography, sport, travel, English topography, gener literature, and of foreign origin. The other catalogu (No. 423) contains particulars of nearly 3000 work relating to mathematics, pure and applied; includin physics, astronomy, meteorology, electricity, enginee ing, assurance, insurance, etc. The catalogues ar obtainable from the publishers upon request.

Our Astronomical Column.

STATISTICS ON STELLAR VELOCITIES.—One of the chief factors in the rapid progress made in recent years regarding stellar distribution and motion has been the substitution of accurate statistical methods for the haphazard investigations of earlier times, which were often based on incomplete material. The *Astroph. Journ.*, June 1924, contains two important statistical papers by Prof. F. H. Seares.

The first deals with stellar velocities, and demonstrates the soundness of Schwarzschild's assumption that the logarithms of the tangential velocities (*i.e.* the velocities deduced from observed proper motion, after correcting for the sun's velocity), for any assigned absolute magnitude, conform very closely to the Gaussian error-curve, sometimes designated "the cocked hat." A similar conclusion is reached for the radial velocities.

The second paper seeks to find a formula for the relative numbers of stars of different absolute magnitudes. The well-known difficulty is present that the extreme dwarfs are invisible unless their distance is small, so that it is impossible to test any region except that adjacent to the sun.

Kapteyn and van Rhijn deduced the mean parallax formula $\log \pi = -0{\cdot}690 - 0{\cdot}0713m + 0{\cdot}645 \log \mu$, m being apparent magnitude and μ proper motion. This is shown to agree well with observation for stars for which M is brighter than 8 mag.; but the number of absolutely faint stars is far greater than that indicated by the formula.

The paper emphasises the urgent need of obtaining more parallaxes of these faint stars.

THE THERMOPILE USED FOR MEASURING STAR MAGNITUDES.—Allusion has already been made in this column to the use of the thermopile for measuring the total absorption by a star-image of a beam of light passed through a photographic plate. The method has the advantages of being free from personality an of giving the integrated effect of the whole imag independently of the distribution of density i different parts of it. It is thus available in reflecto plates to a considerable distance from the centre o the plates in spite of the winged character of th images. Groningen Kapteyn Lab. Publ., No. 32 contains an investigation by J. Schilt which confirm the accuracy and convenience of the method. It ha been applied to several of the Cape Phot. Durchm plates with good results, also to some plates take with the 60-inch reflector at Mount Wilson.

Stars of determined magnitudes are used fo calibrating the curves derived from the thermopil readings; these are taken from the investigations o Seares (Mount Wilson), Chapman and Melotte (Green wich), and Dziewulsky (Potsdam). It is suggeste that the method may usefully be applied to th magnitudes of stars in the Durchmusterung o selected areas.

SOLAR APEX AND VELOCITY.—*Astr. Nach.* 5312 contains a paper by B. Fessenkoff and C. Ogrodnikof on the solar apex and velocity as deduced from th radial velocities of stars of type B. This method o deducing the apex is a useful check on the method from proper motions. The latter is very sensitive t the effect of systematic errors in the older catalogues, as Kapteyn pointed out. The B stars were selected as being of high mass and small peculiar motions.

Four solutions are given, according to the assumed K effect or the shift of spectral lines arising independently of radial motion. They do not differ very largely *inter se*; in that adopted as most probable, K is taken as corresponding to an apparent recession of 3·15 km./sec. According to this, the sun is moving towards R.A. 265·8°, N. Decl. 31·9° at a speed of 21·7 km./sec.

Research Items.

ROUND BARROWS AND THE STUPA.—In the *Ceylon Journal of Science* (vol. i., part 1, section G.) Mr. A. M. Hocart argues for a connexion between the round barrows of prehistoric Europe and the stupa or tope of Indian and Cingalese Buddhism, adapting a theory of Fergusson's in the light of more recent knowledge. Fergusson, in opposing Fergusson's view, derived the stupa from the fire temple, connecting it with the solar origin to which he assigned much in Buddhism. There is, however, evidence that the stupa is essentially connected with relics, like the altar of the Roman Catholic Church, and, according to tradition, was erected over the ashes of an emperor and his family. The name *caitya* given to a tope indicates its connexion with the funeral pile, and the bo-tree invariably associated with the tope in Ceylon, to which the term *caitya* is also applied, is probably a tree planted to mark the spot of cremation. The original object of the round barrow and the stupa, therefore, appears to be identical, the fact that brick is employed in one case and earth in the other being immaterial. Further, it is possible that there may be some connexion between the round barrow and the sacred mounds of Fiji, the link being the Basarh mounds, which appear to relate to the latter through a legend of the origin of earthen mounds which, with certain modifications, is common to both.

PREHISTORIC REPRESENTATIONS OF THE HUMAN FORM FROM MALTA AND GOZO.—Dr. Zammit and Dr. Singer have contributed to the Journal of the Royal Anthropological Institute (vol. liv. pt. 1) a comprehensive study—the first to appear—of the interesting statuettes of neolithic age discovered from time to time in the megalithic structures of Malta and Gozo. The statuettes are, with three exceptions, made from local material, the majority being either of globigerina limestone or clay. In the greater number the most prominent characteristic is their obesity, sometimes, but erroneously, called steatopygia. They are classified into four groups—idealised representations, male and female, portrait models, representations of priests or temple officials, and votive offerings. The first group is that in which the obesity is most marked. The buttocks, thighs, legs, arms, and chest are enormously fat; but the head, when present, and the neck are free from fat, while the hands and feet are in all cases small. Taken in conjunction with other characters, these features suggest that a well-known pathological condition has been taken as a standard and has developed into a ritualistic convention. The figures are comparable with representations of the human form in palæolithic art, and similar figures have been described from Crete, the Cyclades, the Morea, Thessaly, Servia, Egypt, Erythrea, and elsewhere. Certain characteristics, however, separate them from all these except perhaps in the case of Thessaly. It is suggested that they may be a specialised local form, coarse and crude, of an art well known from Crete.

THE MAPPING OF OCCUPATIONAL GROUPINGS.—In a series of Norwegian studies published in the *Sociological Review* for July, Mr. A. Farquharson has made some interesting attempts to map occupational groupings in connexion with a discussion of Aandlesness and its occupations. The principle adopted in the experimental coloured map of about $\frac{1}{8}$ sq. mile of the Aandlesness promontory is based on an eightfold division of simple occupations. These are miner, woodman, hunter, shepherd, upland farmer, lowland farmer, market gardener, and fisherman. For each of these a different colour symbol is used. The derived occupations are indicated by numbers printed over the colour symbols. Thus the derived occupations from mining include smith, tinsmith, stonemason, etc., while, as regards fishing, distinctions are drawn between sea-fishing, fish-curing, and the selling of fish. This classification has the advantage of being evolutionary and indicates the link between simple and more developed occupations, but there are of course cases in which the links are not clear, and could be traced only by research in the particular case and place. In putting forward this tentative scheme, Mr. Farquharson emphasises the need of distinguishing between craft occupations, using the term in a general sense to indicate the making and growing of things; clerical employment; and intermediate occupations such as transport and distribution. The difficulties of this sociological mapping are great, but this attempt is most suggestive of the results obtainable.

VOLCANIC ISLANDS IN THE CHINA SEA.—Two new volcanic islands were reported as having appeared in the China Sea in the eruption of 1923 in approximately lat. 10° 9′ N., long. 109° E. The *Geographical Journal* for August contains a note regarding this occurrence, based on information supplied by the Admiralty. In March this year, H.M.S. *Iroquois* found that both islands had disappeared, and that their sites were covered by water of a depth of about 50 fathoms. The examination also failed to reveal any trace of the 12-fathom bank in the vicinity which had been reported at the same time as the islands. Both the islands and the shallow bank have been omitted from the charts of the China Sea, but caution is advised when navigating in the neighbourhood.

LOAD LINE (ZONES) COMMITTEE.—The report has recently been published of a Committee appointed by the Board of Trade to consider the weather conditions obtaining on the various sea routes of the world, and to advise, having regard to those conditions, to what geographical zones, and what seasons of the year, the application of the special seasonal conditions of loading prescribed by the British Tables of Freeboard may properly be extended. The procedure adopted by the Committee was in the first place to determine the geographical areas in which similar weather conditions exist, and then to study these areas in detail in order to decide what loading restrictions would be necessary. The final recommendations of the Committee are very clearly indicated in a chart of the world printed as an Appendix to the Report. In this chart are shown (*a*) the regions in which winter freeboard should obtain for the whole or part of the year, (*b*) the regions where summer freeboard should obtain for the whole year, (*c*) the regions where weather conditions are more stable than ordinary summer conditions, and in which the deeper "Indian Summer" loading should be permitted, and (*d*) the areas which are specially liable to hurricanes, with a statement in each case of the hurricane season. With regard to the hurricane areas, the Committee did not feel justified in recommending that any new restrictions should be imposed on account of hurricanes, as the number of casualties due to hurricanes, though not accurately known, is small; and in the seasons when hurricanes occur the weather conditions are otherwise favourable. The Committee strongly recommended the issue of a warning to owners and masters of ships which pass through the areas where hurricanes occur that special caution should be observed within those areas, use being made of the rapidly improving facilities for broadcasting weather warnings by wireless telegraphy.

LEFT-HANDEDNESS, STAMMER, AND SQUINT.—The modern tendency to seek for psychological causes for all ailments, whether physical or mental, finds notable expression in a recent article in the *Lancet*, where Dr. W. S. Inman, an ophthalmic surgeon, discusses the origin of squint, left-handedness, and stammer. The connexion between left-handedness and stammering has been observed before, and various attempts have been made to explain it; but always on physiological grounds. Dr. Inman's special contribution to the subject is twofold. While not denying that the causal relation is in many instances to be found in the nervous system, he abandons that line of inquiry and devotes his attention to the discovery of mental causes; and he brings in squinting as a third member of a related group. What he says, in effect, is that left-handedness, stammering, and squinting are but different ways in which the organism responds to emotional stress. The too severe exercise of parental authority in the home, for example, may give rise to left-handedness in one member of the family, to stammering in another, and to squinting in another; or two or three of these peculiarities may appear in any one member. A congenital tendency is, of course, presupposed, for it is well known that each of these defects runs in families. The important point, however, is that the family which is predisposed to any one of these defects is also predisposed to the other two: which of them will actually appear depends upon the general disposition of the person concerned. Dr. Inman thus contends that a self-reliant lad with a strain of perverseness or contrariness in his nature will become left-handed as an unconscious revolt against authority. It is the lad's way of showing that he is "again the government." Gentler natures are prone to respond to the pressure of authority, or the stress of fear, by squinting. Dr. Inman has opened out an interesting line of inquiry which may lead to important results. The cases he cites form strong presumptive evidence of the general soundness of his views.

ANIMAL PARASITOLOGY. — In a recent address (*Science*, vol. 49, pp. 306-310, 1924) on present lines of attack on animal parasitology, Prof. H. B. Ward referred to the recent rapid development of this subject, which has grown more in the last decade than in the whole previous period of recorded science. He pointed out that methods for limiting the attacks of parasites upon their hosts have outrun, in many cases, the information concerning the structure, development and bionomics of the causal organisms, and also of their transmitting agents, if any, and that therefore additional information concerning the parasites is the first necessity for further progress. He emphasised the need for the careful study of the morphology and differential characters of parasites and for examining the original specimens of a species or of material collected in the same locality and from the same host species. He remarked that problems of epidemiology are fundamentally dependent for their solution upon the correct determination of the life-cycles of the parasites concerned, and referred to the confusions which have occurred through faulty determinations. He rightly directed attention to the success of intensive studies on the parasites of lower animals, where continued observation and experimental and close control of conditions, essential for the thorough testing of the results, are possible, and he strongly advocated the closer co-operation of parasitologists and of specialists in the field of medicine.

MINERALS OF THE PRE-CAMBRIAN IN CANADA.—Dr. C. V. Corless recently read a paper before the Royal Society of Arts on the mineral wealth of the Pre-Cambrian in Canada, which is printed in t Society's Journal of August 15. He showed th the Pre-Cambrian rocks occupy an area of so 2 million square miles, and that only a very sm portion of this area, little more than the southe fringe, has been prospected. He pointed out th the Pre-Cambrian rocks in the United States conta the Lake Superior iron mines, which produce the gre bulk of the iron ores forming the basis of the va iron and steel industry of the United States, and t Michigan copper mines, which have long rank among the important producers of that metal, where the same rocks in Canada contain the Sudbury nick copper mines, the Cobalt area silver mines, and t Porcupine area gold mines, and that gold has be found widely distributed throughout a great propo tion of the Pre-Cambrian hitherto investigated. S far as geological investigations have gone, the gener character of the Pre-Cambrian rocks is, broadly speal ing, uniform, and Dr. Corless infers "that simil mineralisation would broadly follow similar geologic conditions because of the wide geological uniformit proven to exist"; he therefore asks the question "Is it not a reasonable certainty that the achiev ments of the past both in discovery and in recover of minerals in but a few per cent. of the total are will be repeated over and over again in the gre Pre-Cambrian area as a whole?" He concluded b stating that he for his part has become fully co vinced that the inference regarding the vast miner wealth of the Pre-Cambrian will be found to be tru and that intensive prospecting within this are promises to yield results of great value.

WAVE-POWER TRANSMISSION.—The Constantinesc system of wave-power transmission has been applie successfully to the synchronisation of the firing c machine-gun bullets from an aeroplane and to th Dorman Long boring machine. In his book "Sonics the inventor investigates this system, taking leakag and friction into account, and obtains a series c equations which show remarkable similarity to thos found in the investigation of long-distance telephone lines. In the *Philosophical Magazine* for July Lieut. E. A. Barclay-Smith attempts to expound th phenomena occurring in wave-power transmission an to formulate an easy method of investigating then from first principles. He also gives an indication o the line of investigation to be followed when the dat are such as will be met with in practice. The essentia feature of this system of power transmission is th production of waves in fluid contained in a pipe b means of a reciprocating plunger at one end; at th other end of the pipe is a motor plunger which i reciprocated by the pressure waves in the liquid. Th pipe may have several branches leading to differen plungers so that power may be received by severa machines. The author first investigates a single pip full of fluid when a plunger starts to reciprocate at on end and neglects friction and leakage, and he show that there is created a series of pressure-waves, eac accompanied by its corresponding particle-velocit wave and travelling to and fro along the pipe, and h explains how the conditions at any point may b ascertained if those existing at some other point ar known. Inertias and hydraulic capacities are the considered, the latter being of two different kinds Then follows an investigation of the simplest practica case, namely, a generator and motor at either end o a uniform pipe. Three cases are examined: (*a* The motor piston is fixed; (*b*) the motor piston i oscillating but absorbing no power; (*c*) the motor i absorbing power. The contents of the paper ar valuable, but will require considerable amplificatio before they can be of service to the practical designe

Germination of Seeds exposed to Low Temperatures.

By H. F. ROBERTS, University of Manitoba.

THIS investigation was undertaken in December 1921. Seeds of thirty species were placed in containers (druggists' ointment tins), one lot being left indoors in the laboratory, at a temperature of 75° F., the other lot being exposed out of doors, for 83 days, from January 9 to April 2. In both cases the seeds were kept perfectly dry. After the conclusion of the period indicated, the seeds of both lots were germinated between blotters for 10 days in the laboratory, at a temperature of 72°-75° F. One hundred seeds were tested from each lot, the germinated seeds being counted on the fifth, seventh, and tenth days. Fifteen varieties of garden seeds, belonging to seven species, gave a germination percentage at the end of 10 days of 67 per cent. to 61 per cent. in favour of the indoor lots. For eleven varieties, belonging to eight species, the germination percentage at the end of 10 days was as 70 per cent. to 66 per cent., also in favour of the indoor lots. The twenty-six varieties gave an average percentage germination at the end of 5, 7, and 10 days of 42 : 36, 61 : 58, and 69 : 65 respectively, for the indoor and the outdoor lots, or a preponderant percentage superiority of 6 per cent., 4 per cent., and 4 per cent. respectively, for the three successive periods, in favour of the lots kept indoors.

From the above summary, it appears that a small average increased germination percentage occurred in the case of seeds kept at laboratory temperature. It was noticed that the seeds of cool temperate species developed a germination percentage higher by 25 per cent. (54 : 20) than those of the warm temperate species kept at laboratory temperature, during the first 5 days of the germination period, although the increased percentage was but 14 per cent. (43 : 29) in favour of the same group exposed to the outside winter temperature. The total germination percentage, however, was approximately the same in both cases.

The mean temperature out of doors for the period of the experiment was as follows, in degrees Fahrenheit: Jan. +3·0, Feb. +0·4, Mar. +24·7, Apr. +41·5, May 60·0.

In the winter of 1923, another lot, consisting of fourteen species, in thirty-three varieties, all of them cool temperate vegetable and field seeds, were exposed as before on January 26. On May 12 the different lots of seeds were tested for percentage of germination. In the preceding year's experiment the germination test was made in the laboratory for plant physiology of the University of Manitoba. In the second year the germination tests were conducted in the official Dominion Seed Laboratory at Winnipeg. The results obtained were as follows: As the average of the summary shows, there was a difference of 4 per cent. in favour of the seeds kept at laboratory temperature,—about 2 per cent. less than the average at the end of 10 days for the twenty-six species and varieties tested the preceding year. At all events, the results, although not conclusive, at least point to a slight diminution in total vitality, as the result of continued exposure to low winter temperatures at the latitude of Manitoba. It should be stated that all the seeds tested were in a thoroughly air-dry condition before the beginning of the test.

Sixty-six varieties, belonging to fifteen species, were tested, including carrot, Swedish turnip, mangel, sugar beet, barley, flax, crimson and white clover, cucumber, cauliflower, celery, egg plant, and cabbage. The total averages for all varieties tested were as follows:

	4-day test.	10-day test.
Inside . . .	56	73
Outside . . .	57	75

There is therefore seen to be practically no difference in the results as between the seeds kept indoors and those kept outside. If some of the individual cases are examined separately, three varieties of carrots gave at the final test 69 per cent. and 68 per cent. respectively for the seeds outside and inside; six varieties of Swedish turnip, 75 per cent. and 75 per cent.; three varieties of mangels, 56 per cent. and 62 per cent.; three varieties of turnip, 71 per cent. and 73 per cent.; three varieties of cucumber, 79 per cent. and 81 per cent.; four varieties of cabbage, 98 per cent. and 77 per cent.

It thus appears, when the details can be taken in numbers sufficient to indicate an average result, that the data agree with the general average. Inasmuch as the data herein are at variance with the general experience of practical men, horticulturists, etc., with regard to the practical utility of chilling seeds, it is concluded that the general factor of moisture is the effective one, and that the layering of seeds in a moist substratum accounts for the effectiveness of the practice, rather than the temperature factor alone.

Barogram Analysis in Weather Forecasting.

THE Italian meteorologist, Francesco Vercelli, has made a laborious study of barographic records from various parts of the world, and various periods and seasons, submitting these curves to a process of periodigram analysis on the lines familiar in tidal investigations, or as applied to the study of seiches in lakes by the late Prof. Chrystal. The results are described in full detail in a booklet published last year in Rome, under the auspices of the Geophysical Institute of Trieste, entitled "Nuovi esperimenti di previsioni meteorologiche."

From the generalised point of view, the barometric curves are shown to contain the well-known diurnal period which is so outstanding in the tropics, various periods ranging between a few days and a month, and an annual period, together with a small "insoluble residue," representing what must be regarded as irregular fluctuations. The amplitudes of these several periods, and other characteristics thereof, differ greatly according to latitude, season, and continentality. If the periodal composition of a given barogram is known, it becomes possible to synthesise its prolongation on the assumption that none of the contained periods die out or others reappear, and thus to make a forecast of the course of barometric pressure for a longer period than is possible by the ordinary synoptic chart method.

Vercelli claims—and the responsibility for the statement must rest with him—to have obtained remarkably good agreement between the predicted and actual continuations of his curves, and to have used this method of weather forecasting with much success in circumstances of grave responsibility on the Italian Front during the War. He indicates the main source of error to be the liability to cessation, or temporary suspension, of any of the component periods, or the reappearance of others. He also points out that the paper in question, discussing the analysis of

single curves, is only the commencement of the subject, since the next step will consist in co-ordinating the analyses of curves from several places; this would greatly enhance the usefulness of this method of forecasting.

The author does not, however, appear to lay enough stress on the fact that forecasting pressure is by no means equivalent to forecasting weather, and that the correlation between rainfall and the height of the barometer at a place, or even the connexion between rainfall and pressure distribution over an area, is none too close from a forecaster's point of view. One has also to consider the tendency of the weather to get into dry or wet "grooves"; for it is well known that during pronouncedly wet spells, downpours occur in passing barometric configurations that would scarcely yield a drop during a dry spell. Moreover, it does not follow that Vercelli's method, even if found practicable in Italy, would answer in England, where it is possible that the relationship between pressure and weather may be rather more complex. It is just such climatic peculiarities we want to discover, and it is not too much to say that even if a universal application of Vercelli's system to weather forecasting proved wholly unserviceable, which is scarcely likely, it could not fail to bring to light any such interesting climatological differences between one region and another. L. C. W. BONACINA.

Wind, Wave, and Swell on the North Atlantic Ocean.[1]

DURING a voyage from Southampton to Trinidad and back by R.M.S. *Oruba* the period of the waves was taken several times daily, and from this their speed was calculated. The speed of the wind was ascertained by means of a Robinson anemometer (lent by the Meteorological Office), due allowance being made for the speed of the ship and the direction of the wind.

The water is very deep from a short distance beyond Ushant, and free from strong currents so far as Barbados. The speed of the wind ranged from 13·9 to 23·6 statute miles per hour. That of the waves was in all cases less, the difference ranging from 1·0 mile an hour to a little more than 8·0 miles an hour. The latter is sufficient to keep a light flag flying. Anything less than 1 mile an hour is reckoned a calm. The difference was not proportional to the speed of the wind; nevertheless a relationship emerges when account is taken of the observations which were made simultaneously of the swell of the sea. When swell and wave ran precisely in the same direction (as sometimes occurred in the region of the Trade winds) and on one day when no swell was recorded, the speed of the wave was so nearly equal to that of the wind that the breeze blowing over the ridges was only equal to the "light air" which barely suffices to give steerage way to a fishing smack. Such a light air would be detected on land by drift of smoke but would not move a wind-vane. Thus there was no longer a battle between wind and wave.

When the swell followed but crossed the wave the difference in speed of wind and wave was greater, and this difference increased rapidly when the crossing swelling swell was meeting, instead of following, the wave. When the waves were much slower than the wind their height was always small, and sometimes their fronts were short and irregular. It was evident that the growth of waves in both length and height was much hindered by a crossing swell, and it ca be safely inferred that the general absence of swell a sufficient reason for the rapid rise of waves upo enclosed seas. When a wind comes on to blow in th direction of the ocean swell with a speed greater tha that of the swell, the growth of large, steep waves very rapid (doubtless even more rapid than the growth from smooth water), but this occurrence relatively rare in the North Atlantic.

The direction of the breaker out at sea was foun to be intermediate between that of wave and swe (the breaker being formed when they override), s that the practice of observing the direction of "th curl on the water" as a method of determining th direction of the wind gives an erroneous result whe ever there is a crossing swell, which is the usu condition upon the oceans. The general run of th waves, on the contrary, gives a trustworthy indicatio of the direction of the wind.

[1] Substance of a paper by Dr. Vaughan Cornish read before Section E (Geography) of the British Association at Toronto on August 8.

Mountain Structure.

THE origin of mountains continues one of the mos controverted problems in geology, because geo logical maps of mountain areas are most difficult t prepare, and the interpretation of mountain structur involves appeal to layers of the crust far too deep fo direct observation. The American Geological Societ has arranged a symposium of nine papers on th development of mountains,[1] which is the best availabl summary of modern opinion on the subject an illustrates its diversity.

The series opens by a masterly sketch by Pro Schuchert of the development of research on orogen from its foundation by H. H. Rogers, and of th evolution of North America, illustrated by 17 map He compares the American school with Haug's vie of geosynclinals, which he rejects as untenabl Amongst several useful new terms proposed "tafrogenesis" for rift valley formation.

Mr. Longwell's paper on Kober's theory is appro priate, as it deals with an extension of the subsidin belt explanation of mountain formation. Kobe reclassifies the Alpine elements to avoid that asym metry in mountain chains which Suess emphasised a their distinctive feature. Prof. Hobbs rejects Suess' arrangement of the Asiatic arcs, and assigns many c them to a direction of movement opposite to tha adopted by Suess.

The structure of Appalachia naturally plays a larg part in the symposium, and is discussed by J. E Woodworth and Arthur Keith, whose conclusions ar opposite. The former adopts isostasy, which Keitl criticises adversely. He attributes the Appalachian to the intrusions of many granitic batholiths; in valuable discussion of rival theories he rejects th shrinkage of the earth, owing to the astronomica disallowance of the necessary reduction in size; bu if the geological evidence for the contracting earth i adequate the astronomers will doubtless find som reconciliation of that fact and their calculations.

The structure and building of the Rocky Mountain is discussed by G. R. Mansfield and W. T. Lee, whos paper is accompanied by appendices by C. E. Va Ostrand and W. D. Lambert. Mansfield reject Kober's view that rift valleys are accompanied b compression, and insists that they are due to tension Lee describes the Southern Rocky Mountains as du to vertical uplift in the restoration of isostati equilibrium.

University and Educational Intelligence.

CAMBRIDGE.—As was reported some months ago, the Rockefeller Trustees offered to build a School of Pathology for the University, and to endow it shortly, if the University could provide from other sources the sum of 33,000*l.* as a share of the total expense involved. It is now announced that Mr. Ernest Gates, of Norfolk, has offered the sum necessary to complete the 33,000*l.*, and is thus enabling the University to accept the generous offer of the Rockefeller Trustees.

LONDON.—A course of 24 university extension lectures on "The History of Science" will be given at Gresham College, Basinghall Street, E.C., by Dr. C. Singer, beginning on September 29. The first lecture will be free. A course of instruction in geography has been arranged for delivery at the Westminster Training College, Horseferry Road, S.W., for one year full-time students and four year part-time students. Particulars of these and other courses of lectures on science, geography, history, literature, economics, art, etc., may be had from the Registrar, University Extension Board, University of London, South Kensington, S.W.7.

MANCHESTER.—In connexion with the department of Bacteriology and Preventive Medicine, a diploma in bacteriology has been instituted and a course of instruction for graduates in medicine or in science will be started in October. It is requested that intending candidates for the diploma shall send their names to the director of the Public Health Laboratory, York Place, Manchester, from whom further particulars can be obtained.

OXFORD.—Applications are invited for two research assistantships in the Institute of Agricultural Engineering. Candidates must have had specialised training and experience in advanced physics and electrical engineering respectively. Particulars and application forms are obtainable from the Director of the Institute, 65 St. Giles', Oxford.

UNIVERSITY COLLEGE, Reading, and the Berkshire Agricultural Instruction Committee invite applications, up to September 29, for the post of Instructor in Beekeeping for Berkshire. Particulars may be had from the Agricultural Organiser for Berkshire, University College, Reading.

APPLICATIONS are invited for the professorship of Electrotechnics in the University of the Witwatersrand, Johannesburg. Particulars of the position and form of application are obtainable from the Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2. Applications for the post and copies of testimonials must be sent to the Secretary by, at latest, September 30.

THE Educational Directory, 1924, published by the United States Bureau of Education, containing some 15,000 names and costing only 20 cents, must be invaluable to educationists in the United States, and is not without interest in other countries. The names given are those of presidents, deans, superintendents, and other administrative officers, and there are useful lists of boards and foundations, libraries, associations, and periodicals. The extent to which the summer school system has developed in America is indicated by a list of nearly 900 summer schools.

Early Science at the Royal Society.

September 13, 1666. The Society being taken up for the most part of this meeting with the consideration of the place for their future meetings in that time of public disorder and unsettlement by reason of the late fire, was thereby hindered from making experiments, and discoursing of philosophical subjects, as they used to do.

1677. Ordered, that Mr. Boyle, Sir John Hoskyns, and Mr. Hill, or any two of them do at ten of the clock in the morning go to the widow of Mr. Oldenburg, late secretary of the Society, and demand, receive, or take order for securing, for the use of the Society, all such goods, books, and writings belonging to the Society, as were or had been in the possession of her, or of her late husband.

September 14, 1663. Mr. Oldenburg mentioned, that Mr. Beal was willing to engage in the observation of the weather, and in registering the changes thereof; and that he hoped to set the same at work in other parts of the country; desiring to be furnished with thermometers of the same figure and size. Whereupon Mr. Hooke was ordered to give the operator directions to provide a dozen sealed thermometers with spirit of wine, to be sent to Mr. Beal, and into other parts of the world.

1664. An account was given by the president of some experiments made on the top of St. Paul's steeple: 1. To measure the vibration of a pendulum of 200 feet long. 2. To discover the difference of the weight of bodies on the top of the steeple and below. 3. A repetition of the Torricellian experiment.

September 17, 1662. Sir Robert Moray mentioned a French gentleman, who having been some time in England, and being present at a meeting of the Society, took notice, that the nature of all trees is to run altogether to wood; which was changed by a certain method of cutting them, whereby they were made, contrary to their nature to bear fruit; and that according as this cutting was performed with more or less skill, the more or less fruitful the tree would be. A proposition was offered by Sir Robert Moray about the planting of timber in England, and the preserving of what was then growing.—Dr. Charlton read his discourse entituled "Apparatus Phonocampticus: or what inquiries are principally to be made by such, who would attain to the certain knowledge of the nature of echos," which was ordered to be entered into the book of histories and theories.

September 18, 1661. Mr. Croune produced two experiments, one of the compression of the air with quicksilver in a crooked tube of glass, the nipt end of which broke; and the other with a cork kept down at the bottom of a cylinder of water in a vessel perforated at the bottom, over which the cork was laid; upon stopping of which foramen, and the pouring in of water, the cork immediately rose.—Mr. Boyle gave an account of his having made the former of these experiments by compressing twelve inches of air to three inches, with about an hundred inches of quicksilver.

1666. Mr. Hooke showed his model for rebuilding the city to the society, who were well pleased with it; and Sir John Laurence, late lord mayor of London, having addressed himself to the society, and expressed the present lord mayor's and aldermen's approbation of the said model, and their desire that it might be shown to the King, the president answered, that the society would be very glad, if they or any of their members could do any service for the good of the city; and that Mr. Hooke should wait on them with his model to the King, if they thought fit to present it; which was accepted with expressions of thanks.

Societies and Academies.

PARIS.

Academy of Sciences, August 18.—M. Guillaume Bigourdan in the chair. Notice of the death of J. B. de Toni, Correspondant in the section of botany.—F. E. **Fournier**: Remarks on the interpretations to be given in future to the three special signals defined in the author's note on safety manœuvres for steamships passing each other in fog, published in the *Comptes rendus*, August 4.—S. **Winogradsky**: The microscopic study of the soil. A detailed description of the technique adopted for the direct observation of the soil bacteria, together with a short account of the results obtained.—E. **Mathias**: The noise of the lightning flash. The theory is propounded that the electrical discharge produces endothermic compounds of oxygen and nitrogen of the type O_4, N_4, O_6, N_6 and that the noise of the flash is produced by the explosive decomposition of these substances. According to this theory the flash and noise are not produced simultaneously. No experimental evidence in support of the theory is given.—Charles **Nicolle**: Contribution to the knowledge of obscure infections. Examples drawn from the experimental study of exanthematic typhus. The term *infection inapparentes* is given to a type of acute septicæmic infection, existing exceptionally in the guinea-pig and frequently in the rat. There is no rise of temperature, and the existence of the disease can only be recognised by inoculation into other animals: the condition is quite distinct from what has been termed latent infection.—H. **Mineur**: The analytical theory of continued finite groups.—M. **Paschoud**: The problem of uniform regime in a fine tube the section of which is an isosceles right-angled triangle.—Carl A. **Garabedian**: Four methods for solving the problem of the rectangular beam.—Antonio **Cabreira**: The determination of geographical latitude, any three altitudes and the declination of the star being known.—Ernest **Esclangon**: The total eclipse of the moon of August 14, observed at the Strasbourg Observatory.—L. **Dunoyer** and P. **Toulon**: Some electro-mechanical applications of arc relays with external sheath.—Carl **Benedicks**: Method for the determination of the density of iron and of other refractory metals in the liquid state: an extension of the hydrostatic method of Dulong and Petit. The density of liquid iron at 1540° C. was found to be $6{\cdot}92 \pm {\cdot}07$.—C. **Gutton** and G. **Laville**: Electrometric measurements of very small alternating potential differences.—R. **Bureau** and A. **Viant**: Meteorological conditions and the appearance of certain atmospheric disturbances in receiving apparatus of wireless telegraphy. Atmospherics are always connected with invasions of polar air and are removed by the arrival of a warm front.—André **Graire**: The reversibility of the reactions of sulphuric acid formation in leaden chambers. Evidence of the reduction of sulphuric acid to sulphur dioxide by nitric oxide, reversing the ordinary reaction forming sulphuric acid in the leaden chamber.—Mme. Pauline **Ramart**: Molecular transpositions. Identification of the products of dehydration of 1.1.3-triphenyl—2.2-dimethyl—1-propanol.—H. **Gault** and B. C. **Mukerji**: The formation of hydrocellulose.—G. **Vavon** and A. **Couderc**: The isomerism of menthol and neomenthol. The addition of hydrogen to menthone, in the presence of platinum black, gives a mixture of stereoisomers in which neomenthol (cis) predominates over ordinary menthol (trans).—R. **Fosse**, Ph. **Hagene**, and R. **Dubois**: Researches on a new method of quantitative analysis of cyanamide in its calcium compound.—P. **Nottin**: The estimation of maltose in the presence of other redu sugars by means of Barfoed's solution.—A **Schoep**: Sklodowskite, a new radioactive min This was found in the Belgian Congo, in a layer taining several uranium minerals. Its composi is $MgO \cdot 2UO_3 \cdot 2SiO_2 \cdot 7H_2O$ and it has tellurium, ni and alkalies as impurities.—R. **Verneau**: Re prehistoric discoveries in Indo-China. These dep were found in caves in the Bac-Son limestone ma and have furnished several thousands of s implements.—L. **Blaringhem**: The degenerescc of flax.—L. **Emberger**: Contribution to the st of the formation of plasts in plants.—G. **Ram** The properties of diphtheric anatoxine. The toxine, the preparation of which was describe an earlier communication, retains its immuni properties for long periods (twelve months) if in an ice box (3° to 4° C.). Keeping does not dev any toxicity, and the properties are unchanged a heating to 65°-70° C. for one hour.—— **Simion** and André **Lancien**: The influence of the cinna radicle on the stimulation of the hæmatopoi organs.

FRIDAY, SEPTEMBER 19.

CERAMIC SOCIETY (Refractory Materials Section) (at the British Emp Exhibition.—(For Papers to be communicated see above.)

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—*Red Book* Ni (Affiliation of Photographic Societies with the Royal Photograp Society). The slides selected from the Affiliation lantern slide co petition will be shown on the screen, and a criticism on the slides w be made by S. L. Coulthurst.

Supplement to NATURE

No. 2863 SEPTEMBER 13, 1924

The History of Scientific Thought.

By W. C. Dampier Whetham, F.R.S.

THE earliest form of history is a chronicle of priests and kings with their attendant worshippers and warriors. The misty dream of godascended heroes passes into the clear vision of the lered march of Roman legions; the picturesque geant of medieval bishops and barons vanishes in e smoke of Bosworth field; and the sound of Drake's ns, drumming the Spaniards up the Channel, melts o the strains of a Te Deum, sung in Notre Dame f another victory over Marlborough.

Then Clio discovers politics, and tells us of statesmen d of constitutions. Pericles and Cicero, Richelieu d Walpole, Magna Charta and the Petition of Right, e Declaration of Independence and the French evolution (with appropriate footnotes on contemrary literature and art), are acclaimed as the proper udy of mankind. The old idea of a Garden of Eden a golden age of heroic kings in the past changes into e equally pathetic delusion of certain and continued ogress in the future, necessarily linked with the owth of political democracy in the present.

So historians taught when our fathers were young. hen came Thorold Rogers and William Cunningham, ho first saw the importance of economic history, hile Maitland was putting new life into the chronicles Law and Constitution by the study of records. nderlying the froth and glitter of politics and war, e were shown the deep and steady currents of economic hange. Control of the trade routes of the ancient orld, the rise of European prices due to the gold of lexico and Peru, the coal of England burning into ower in the pioneer factories of the world, were realised s more mighty than the beauty of Helen or the valour f Achilles, the will of Popes or the ambition of Kings, he genius of Napoleon or the lure of Reform Bills. nd the believers in sudden Utopias, disillusioned by his time of political reform, hastened to become conomic socialists.

But now men begin to ask how these resistless urrents of economic change are started, and what letermines the channels in which they flow. It is lear that our varying control over the resources of Nature is one factor involved. When bronze could be sed instead of stone and flint, when fresh-forged iron replaced the softer bronze, new industries appeared, and the efforts of men were perforce turned aside to develop and exploit them. The making of gunpowder pierced the knight's bright armour and levelled the baron's frowning walls, to spread abroad the King's peace and liberate the trade of towns. Tull's discoveries in the art of growing field-crops, and Bakewell's study of the methods of stock-breeding, gave food for the rapidly growing population, called into being by the energy of coal, converted in the factories built to meet the inventions of Watt and of Arkwright.

This harnessing of Nature's fiery steeds of power is one of the two functions of that ordered knowledge we call science, and, conversely, the material wants of man give one of the two motives from which pure as well as practical science springs. Geometry arose from the need for the repeated mensuration of land after the yearly flood of the Nile; astronomy began as the bye-play of Chaldean astrologers, seeking, by the dim light of the stars, to peer into the future and thus control the destinies of man; thermodynamics was developed to explain and improve the working of the steam-engine.

But another desire is also at work to generate science, and another function is fulfilled by science when born. Man does not live by bread alone. The longing of the soul for light, of the brain for knowledge, is a nobler if a rarer instinct than the craving of the body for food and shelter. The mystery of existence, the eternal riddle of the Sphinx, moves the mind of the philosopher, and, when he learns to humble his hopes and advance step by step on the slow road of observation and experiment, he becomes a man of science and gains an ever-increasing insight into the secrets of Nature.

So it is that history, to become a complete record of man's story, must take account of his intellectual as well as of his material achievement. Thus alone, when the history of thought is combined with that of action, can we watch in its fulness the great human drama, and write in worthy form a Universal History of the World.

Moreover, to do this as it should be done, we must call to our aid the transforming magic of literature. Our poets must not only sing of burning Sappho or the hills of Rome, of Ivry or of Waterloo, of fights for

freedom or of legal progress broadening down from precedent to precedent. They must tell us also of Newton and of Einstein; of the busy laboratory and the mountain observatory; of the spiral nebula whirling from its arms new stars into the dark abyss of space, and the hundred million years of organic evolution; of the lion-haunted dreams of early cave-men, the rise and fall of succeeding civilisations in the long history of the world, and the majestic march of modern knowledge—perhaps but starting on an illimitable progress towards the moral and material betterment of all mankind, perhaps doomed to check and dissolve once more amid the social and economic dangers of our great democratic experiment. There is romance enough in the story of the past, in the veiled mystery of the future, to give a theme worthy of Shakespeare or of Sophocles.

This vision of science as the uniting link between the intellectual and the practical efforts of man, the worthy subject of history and of literature—a vision hitherto seen by few—is at length becoming clear to many. Darwin fluttered some ecclesiastical dovecots; but now for thirty years a cumulative series of striking discoveries has awakened the imagination of all educated men. Röntgen's X-rays, the sub-atomic electron of Thomson, the radioactive disintegration of matter revealed by Rutherford, are paralleled on the biological side by the tracing of the source of malaria, the detection of vitamins, and the application of Mendel's researches to the breeding of new varieties of cereal crops. The War enforced the lesson. Victory was impossible without the aid of the physicist, the chemist, the biologist, and the engineer; and peace cannot bring prosperity and contentment until the electrician has led power about the land, and the economist taught us how best to use and distribute its products.

We see, therefore, a great quickening of interest, not only in contemporary science and its possible applications, but also in the story of scientific development in the past and in the lives of those who have made it. We need but turn over the pages of NATURE for the last few years to see what a change has taken place. Book after book has recently appeared dealing with some aspect of this wide subject, and NATURE itself has helped, both by notices in its editorial columns and by such serial publications as the Calendars of Scientific and Industrial Pioneers and the abstracts of Early Science at the Royal Society.

The universities and schools also are showing more interest in this aspect of science. Mr. R. T. Gunther, led by a chance finding of a collection of apparatus "locked up in a dark cupboard in Christchurch, all smothered with the dust of ages," is publishing a series of studies of early science at Oxford, and Dr. and M Singer carried on notable research there on the histo of science, especially on the biological and medical sic before they moved to London, where a Universi course of study in the history, principles, and metho of science, leading to an M.Sc. degree, has been esta lished. Sir Clifford Allbutt gives occasional lectur at Cambridge on the history of medicine, and S Arthur Shipley on the development of biology.

In schools, nearly all boys now learn some scienc and, both for those who are specialising in it and f those whose main intellectual interests lie in other fiel of thought, it is well to gain some knowledge of t course of its growth, even to read some of its classic writings. The reports of the yearly conferences schoolmasters show an increasing appreciation of t advantages of this mode of treatment.

Education is searching for a way of presenting t new humanism. When the works of the writers Greece were rediscovered at the Renaissance, they we welcomed, not only as history and literature, but al as containing philosophy and science far in advance anything then known to the modern world. It w natural and right that school studies should be found on classics, and a classical education was then, and un recent times, the best available. It survived its usefu ness, and the inevitable reaction brought into prom nence a somewhat academic treatment of mathematic and a rather inhuman and too odoriferous scienc Such studies could not give a complete education, ar a tendency to emphasise once more the benefits classics became manifest.

Science, however, has now reached heights and depth far beyond those that could be touched by the Greek and philosophy in the light of science has assimilate the best part of Greek thought and passed on. Histor and archæology trace the rise and fall of five or mor civilisations, in which that known to Herodotus an Livy is but the last before our own, and possess a wealt of records in which a student may learn the deligh of research at first hand. The literature of Europe i the last three hundred years can show masterpieces no unworthy of ancient times, and the Gothic cathedra is as noble a building as the Athenian temple.

It is essential to train modern youth to understan and appreciate modern action and modern thought and a modern humanism is now possible which view classical learning in its right place in a greater whole In that humanism the history of scientific thought fill a worthy place, and, with a more intensive study o some science itself, may give that open mind and spiri of reverent inquiry into truth which is the essence o scientific method, and the best object of a libera education.

Science and Literature.

THE rather widespread feeling that science and literature are, in some way, opposed to one ther seems, at first sight, inexplicable. For we can that science is merely a way of ordering experience terms of certain fundamental principles and con-ts, and that literature is a way of ordering experi-e which employs different principles and concepts. position could arise only if one of these methods fessed to be exhaustive and declared that there was room for the other. But science certainly does make that claim. No scientific man asserts that comprehension of a certain region of experience t is given to us by Shakespeare's plays is contained ny scientific treatise, and although we are frequently d that some poet or philosopher has anticipated some at scientific theory—*e.g.* Einstein's—it is probable t this statement is not intended seriously. Yet it rue that there are many literary men who regard nce as if it were, in some way, opposed to rature.

here seem to be various reasons for this attitude. the first place, it is becoming increasingly obvious t a literary education is only half an education. It still possible for the writing of a poem or the writing a novel to be referred to as "the highest of human ivities," but the statement is not now so generally ieved. An increasing number of people are begin-g to believe that the creation of a great scientific ory may be as great and significant an achievement, high an activity, as the creation of a great work of re literature. From this human, all too human, nt of view we can quite imagine that some literary n find science a sort of rival, and a dangerous rival, literature. But we must admit that this explana-n covers only a small part of a widespread attitude. more important element in the "opposition" to ence is due to the dislike of the materialistic ilosophy with which science was, until recently, pposed to be associated.

That the scientific man is a dull materialist, in-sitive to beauty and incapable of profound emotions, or has been, a commonplace amongst literary ists. A botanist, as is well known, is a man who ows everything about a flower except that it is utiful. That these purblind creatures have an rdinate appetite for facts, and a curious, abnormal leverness," is freely admitted. But since they are nd to everything that makes life to other people rth living, know nothing of the artist's raptures nor the hopes and despairs of passionate natures, lieve that nothing is real except what they can put a test-tube, they must be treated, as Nietzsche says, as mere instruments. They are more costly and exquisite versions of their own galvanometers and spectroscopes. In the great company of prophets, seers, and poets, they have no place. They are merely measuring machines, to be made use of by their betters.

This is Nietzsche's view and it is not uncommon. Is there any justification for this view? It must be admitted that some scientific men almost warrant the caricature. It is a peculiarity of science, as distinguished from the arts, that valuable results can be achieved by mere industry. The possession of a telescope, and of an abnormal capacity for sitting still, have sometimes made their owner immortal. It is true that eminence in science can sometimes be achieved by a man without insight, without imagination, by dint of the unexciting virtue of conscientiousness. Valuable as these men are to science, they have no perceptible existence except in conjunction with a laboratory. To the literary man, for whom greatness is almost synonymous with the capacity for experiencing and expressing profound emotions, the eminent man of science may be a negligible human being—"a mere specialist." It is appropriate that such a being should adopt materialism as a philosophy. He finds nothing in his own soul which seems unlikely to be the outcome of the mutual impacts of little billiard balls, and, being unaware of his narrow limitations, he suggests that this hypothesis will cover everybody's experience. To some of the greatest literary artists of the nineteenth century, scientific materialism, as it was popularly understood, was the final proof of the inadequacy of the scientific mind. It is unfortunate that science is so technical, for it means that non-scientific people cannot distinguish between the great creator and the merely industrious worker, and that only a debased and distorted version of a scientific theory gains currency amongst them.

But while the contempt for and dislike of science manifested by such great artists as Tolstoy and Dostoevsky was largely founded on a misapprehension of what science is, the change which has occurred in the attitude of literary men towards science is certainly connected with the fact that materialism is no longer so vehemently preached by scientific men. Such great scientific theories as the electrical theory of matter and the theory of relativity have finally destroyed, it is felt, that old Victorian mechanical universe, with its "iron laws." The universe has become "enjoyable," in Maxwell's sense of that word when he says that the necessary condition of the enjoyable is that the mind

should believe in the existence of a law and yet have a mystery to move about in. In the new universe of science the poet feels that he has room to exist. Such feelings are not, perhaps, based on reason. It might be difficult to justify them, but even the man in the street feels that the "atmosphere" of the modern scientific universe is very different from that of the universe of, for example, Haeckel. For this reason there has been a change in the literary man's attitude towards science. He is even willing to admit that scientific men of Einstein's rank may, in virtue of their imagination and passion, be ranked with great artists. But although a scientific man may be ranked as an artist, there remains an essential difference between a scientific work and a work of art.

That a scientific treatise may be exceedingly well written nobody will deny. That scientific men may show a delicate and catholic taste in literature, or, indeed, in any art, is also quite true. But it does not follow that a scientific treatise, however well written, can ever rank high as a work of literature. It seems that one criterion of the greatness of a literary work is its "immortality." To achieve this it must deal with subjects of permanent interest, and its presentation of them, although it may not be exhaustive, must be of such a kind that it cannot be superseded. Even where the ostensible subject-matter is of comparatively little interest, the real subject-matter—usually the personality of the author—has this quality. Very few people are interested in the subject of urn-burial, but many are interested in Sir Thomas Browne's unique reflections on that subject. Now it is of the essence of the scientific treatise that it deals with the transitory, for it is of the essence of the scientific conception of truth that science can continually advance; and it happens that a scientific argument is not a favourable medium for the expression of the most generally interesting characteristics of an author's personality. Even the best written of scientific treatises, and written by the best scientific men, such as the Dialogues of Galileo, have no longer the living interest that much older works of literature possess.

The reason is not difficult to discover. This apparent weakness is due to the very strength of science. Science is universally communicable and verifiable, or it is not science. It makes appeal, therefore, to just those faculties and interests that are least individual in men. It is impersonal, as we say. A scientific theory is an interpretation of experience which is valid for all minds precisely because it is not concerned with experiences which are individual. A scientific man has, potentially, all rational creatures for his audience. The artist can make no such claim, but he penetrates to a greater depth. At present the greater part of every man's experience lies outside t scientific picture and, for the majority of men, is far the most interesting part of his experience. T arguments for the belief that the sun goes round t earth, however wittily presented, are of little intere now except to psychological historians. But huma nature has changed much less than scientific theori and a presentation of unrequited love, or of goodne triumphant in adversity, can still be pertinent to pr sent problems and has lost nothing of its illuminati power for being centuries old.

This is not to say, of course, that the deepest hum passions are not concerned with science. Kepler, describing his triumph at his discoveries, wrote so of the finest passages in literature, but those passag describe his emotions, not his discoveries. Th convince us that science may require the highest a deepest emotions for its service, that a great man science may truly be a great artist, that he may gi to science a passion and creative imagination that oth men give to religion. But that does not make problems eternal, or of permanent interest. The fa of a scientific treatise, as Huxley has said, is to be p of the rubble which forms the foundation of the n building.

The distinction between the scientific treatise a the work of literature, therefore, is connected with old question of matter and form. What Shakespe has to convey cannot be otherwise conveyed, bu student may fully master Lagrange's conception dynamics without having read one line of Lagran There is, then, an essential difference between scie and art, and, however far science penetrates i regions of experience it has scarcely yet touched, th will always remain an essential difference. This d not mean that the artist can ignore science. A matter of fact, the scientific outlook affects literature influencing the artist's emotions. Darwin's theory, example, has had a great influence on modern lite ture. The influence of science is indirect; it is important factor in shaping the *Zeitgeist* that prev at any given time, and so influences not only the a but also philosophy and religion. But there can no opposition between science and art except in sense that the artist may feel himself to be in rebell against the spirit of his age, a spirit largely due to scientific outlook current in his time, or more probal that was current a generation or two before his. artist, therefore, does not ignore science; the fact he cannot escape it. When, however, he conce himself merely with the expression of scientific fac theory, and not with the spirit of quest and discov the chords he strikes must fail to find unive response in the human heart.

World List of Scientific Periodicals.

By F. W. Clifford.

It is difficult to conceive a publication which would be of greater value to scientific workers in Great Britain than that which is the subject of this article. Research workers in the realms of science, constantly confronted with references to periodical publications to which they have not immediate access, have often expressed the need for an authoritative list of scientific journals, together with an indication of the British libraries where they can be consulted. In the absence of this information, provincial workers are compelled to spend money and ill-spared time in journeying to and from London for serials which may perhaps be contained in a library nearer at hand.

Such a project has frequently been discussed and been commenced. The Panizzi Club, composed of senior officers of State, Universities, and Professional libraries, got well ahead with a Union list in the early months of 1914, but the War intervened and the work so well commenced by Mr. E. W. Hulme, then Librarian of the Patent Office, came more or less to a standstill. This earlier effort was practically forgotten, when, in 1921, the need for such a list was again urgent, and the Conjoint Board of Scientific Societies appointed a small committee to devise a practical scheme for the compilation and subsequent publication of a World List of Scientific Periodicals.

The Trustees of the British Museum were approached, and recognising the importance of this work to scientific research and bibliography, they consented to allow the compilation to be undertaken by the staff of the Museum. With this very material assistance, and financially fortified by the private guarantees of two well-known men of science, the Conjoint Board felt able to proceed with the proposal. Fortunately, at this critical period, however, the Carnegie United Kingdom Trustees expressed their willingness to add a substantial guarantee if the original scope could be somewhat widened. This action very considerably smoothed the way, and steady progress was made with the List. When the Board itself was dissolved in 1923, the original Committee was formed into a Limited Company so as to ensure the publication of the completed work.

It is intended that the List shall be issued in two parts. The first part is now in the press and will probably be published during the present year. This portion consists of a list of more than 25,000 scientific serials in existence in 1900, or originating between that date and the year 1921, whether still current or not.

Each serial is arranged alphabetically under its title, *e.g.* the Philosophical Transactions of the Royal Society will be found under "P" and not under "Academies, London." The items are numbered consecutively, and these numbers will be used in Part II. to identify the periodical. It will be recognised that in the arrangement of a list of this kind there may be several opinions as to the precise order which should be followed. The fact, however, that Prof. A. W. Pollard, until lately the Keeper of Printed Books in the British Museum, has acted as the editor, should more than guarantee that the final decision has been made in a manner which should meet with the approval of the bibliographer and fulfil the requirements of the scientific worker, whose references to periodicals are so often in a very abbreviated form.

The second part, or Index Section, will indicate in what libraries in the United Kingdom a copy of any of the serials in Part I. can be consulted. Sets of the sheets of the first part are now being circulated amongst important libraries, general and special, both in London and in specified provincial centres, for the addition of this information.

In the provincial centres the aid has been enlisted of certain professors and librarians, who are acting as local secretaries to co-ordinate the information as to periodicals taken in their respective districts. This laborious, but most valuable, work has to be carried out promptly, or otherwise the publication may be delayed. At a later date, perhaps, it may not be out of place to disclose the names of these enthusiasts, to whom scientific workers will always be indebted.

It may be well to mention that the World List is not intended to be a catalogue of the periodicals in any given library. A moment's thought will show the practical impossibility of giving all the libraries containing English journals of considerable circulation. In the case of these, the local secretaries have been asked to exercise discretion as to whether there is any need to indicate the existence of more than one complete set in their town. It would, however, be easy for any centre to use the World List as a catalogue of periodicals in that area by the simple means of stamping with a rubber stamp opposite each periodical possessed by the individual libraries comprising it. Or, as Part I. of the World List is printed on one side only, the entries could be cut and mounted on cards.

The List should also be of service in encouraging co-operation between large libraries in the direction of lessening duplication in their immediate neighbourhood, with the result that funds may be released for the purchase of additional periodicals, and in consequence increase the total number of periodicals contained in that area. At the same time such a survey would

show those responsible, how well, or ill, the research worker is catered for with regard to periodical literature in the respective institutions.

A comparison of the World List of Scientific Periodicals with the "Gesamt Zeitschriften Verzeichnis" shows that the former contains 25,000 whilst the German publication contains but 17,190. The French "Inventaire des périodiques," of which the first number has recently been issued, is not far enough advanced to ascertain the number of periodicals which will eventually be covered by it, but the letter "A" contains 2357 entries as against 2649 in the English production. No conclusion can be drawn from the latter figures, as the arrangement of the entries is not quite the same as that in the World List. Also the information as to libraries refers only to those in Paris itself.

This census of periodicals shows that the scientific journals are steadily increasing in number. Many new serials have commenced life since the War, and n Academies founded from patriotic motives are co mencing to publish printed memoirs. Is it not ti that a halt should be called? Would it not be possi for the older Academies to set an example by encour ing the publication of their own communications in specialised journals? The scientific worker would th have his material more or less collected instead contained in an academic "mixed grill." The searches would reach without delay those most terested, whilst details of abstraction, etc., would very much simplified.

In conclusion, whilst no one library can be expec to contain all the periodicals mentioned in this mo mental work, every library should at least contain copy of the World List in order to direct inquirers the nearest library where a particular periodical m be seen. Scientific research workers will in due ti find that it is indispensable to them.

The Library Association's Subject Index.

SINCE 1915, "The Subject Index to Periodicals"[1] has been issued annually by the Library Association in the form of eight Class-Lists, except for the period 1917–19, when the lists were triennial. The Class-Lists are: A, Theology and Philosophy; B-E, Historical, Political, and Economic Sciences; F, Education and Child Welfare; G, Art and Archæology; H, Music; I, Languages and Literature (Part 1, Classical, Oriental and Primitive; Part 2, Modern and Bibliography); K, Science and Technology; L, Author Index to A-K, and List of Periodicals indexed.

The Index is a classification of articles of reference value selected from an examination of close upon 600 periodicals, English and foreign. The entries are minutely classified under the alphabetical subject headings of the Library of U.S. Congress, and are annotated where it is desirable to define with greater precision the scope of articles. The unbound numbers of periodicals sent for indexing are filed for reference and lending purposes. Any subscriber to the Index can on application obtain the loan of specified articles on payment of the return postage. Further, he can require the editors to furnish him with a list of articles under specified headings in continuation of the last printed Class-List.

Thus subscription to the Index on the part of a small rural or town library raises the status of that library to that of a research institution, for the Index places its readers in touch with the latest developments in thought, policy, and action in all departments of human l while it maintains a library of serials for reference wh is not only larger than the corresponding collecti in the average municipal reference library, but probal also contains serials not to be found in the library the British Museum itself. This work of the Libr Association could not have been carried out with some external assistance. Generous pecuniary assi ance has been forthcoming from the Carnegie Uni Kingdom Trust, while free quarters have been found the editorial staff of the Index and its nucleus l collection in the great National Library of Wales Aberystwyth.

It should be noticed that "The Subject Index Periodicals" was planned at a time when "The Int national Catalogue of Scientific Literature" was s in existence. Hence the Index was to a great ext designed to bridge the gaps which that publication l unfilled. With the discontinuance of "The Int national Catalogue," however, the question of the ordinated publication of indexes to scientific periodi literature once more comes to the front. This subj was brought before the Conference on Bureaux Information and "Special" Libraries held at Hoddesd on September 5-8. It may be taken for granted th international co-operation has failed and that the futu organisation of scientific literature must be effected a national basis.

Secondly, it should be remembered that the State h a well-defined interest in this matter, and should called upon to shoulder its share of responsibility. F example, the principal repositories of the serial lite

[1] Annual subscription, 4*l.* 4*s.* (Agents: Grafton and Co., 51 Great Russell Street, W.C.1.)

re of art, education, science and technology are to be found in the State collections. In the case of many foreign serials, the only accessible copies are filed in these libraries, and naturally their curators possess the requisite qualifications for dealing with the highly specialised class of literature which they control.

Co-ordination in indexing requires the acceptance of a common scheme of classification and headings, and an agreed form of index entry. Further, the financial prospects of success under such a scheme are materially improved if the indexes produced are uniform in format and style and are published by a single agency. These conditions being granted, the actual indexing can be carried out in any home or library.

This method of indexing supplies a sound basis for development and negotiation. Any of the Library Association's Class-Lists could be split into smaller units —and some would no doubt benefit by such division, namely, B-E, historical, political, and economic sciences, and K, science and technology. A suggested inclusion of another 50 or 100 additional periodicals in any Class-List could be met if the State librarian, or secretary of the society in question, were prepared to supply the index entries and supervise or edit the extended Class-List. Any development in this direction would be welcomed by the Library Association.

The Index has now become practically self-supporting. It has been run by voluntary aid—one editor alone being in receipt of a modest salary. Finally, the Association has pledged itself not to treat any profits made by its publication as the property of the Association. Such profits will go either to a reserve fund or, more probably, towards the reduction of the price of its Class-Lists. It is scarcely necessary to add that the accounts of the Index are duly audited by a chartered accountant.

Reports of the Progress of Applied Chemistry. Issued by the Society of Chemical Industry. Vol. VIII., 1923. Pp. 618. (London: Society of Chemical Industry.) 12*s.* 6*d.* net, post free.

The annual publication of these reports is not an event that evokes widespread interest or comment, yet the reports are always welcome to a goodly number of specialists. They are not original in the strict sense, because they are mainly compilations from the abstracts of original papers that have appeared during the year under review. Nevertheless they are very useful: they save the worker much valuable time; they instruct him concerning advances in branches of applied chemistry of which he has no expert knowledge; and if he believe what his testimonials state, that he has "a good all-round knowledge of chemistry," after reading these reports he will lose his conceit and confess his general ignorance.

The chief difficulty connected with publications of this kind is that the expert is too frequently a bad writer; and the chief defect is the absence of critical insight. It is, of course, no easy task to assess the value of developments that happened yesterday, but more attempts in this direction might usefully be made. Further, the reports would gain in lucidity—and the cost of publication could be materially reduced—if the phraseology were rigorously pruned; redundancy of expression and other forms of "journalese" are too common in the present volume.

A welcome feature in many of the reports is the inclusion of summaries of the trend of events in the economic sphere: a practice which should be extended, especially as there is now no single ephemeral publication which provides, regularly and systematically, information of this kind on all branches of industrial chemistry. The pending publication in the United States of *Chemical Reviews*, which will be issued quarterly and will deal with recent progress, may help to fill the gap which is now apparent in our chemical literature. If the reviews are critical and constructive as well as informative, the specialist may prefer them to annual catalogues of facts; but he will need, and should acquire, both. The comparatively small sale of annual reports of the kind we are used to is a distinct reflection upon English-speaking chemists, and no one will criticise the Society of Chemical Industry for maintaining in adverse times its expenditure on this useful publication, which falls well within the scope of its legitimate activities and of the wishes of its founders and benefactors.

Chemical Encyclopædia: A Digest of Chemistry and Chemical Industry. By C. T. Kingzett. Third edition. Pp. x+606. (London: Baillière, Tindall and Cox, 1924.) 30*s.* net.

Within the last few years several works of this character have been published under various titles. Consequently the fact that the present volume has attained a third edition within a comparatively short time shows that it has supplied a well-defined want, and indicates that a knowledge of chemistry is becoming more and more indispensable to growing sections of our population, such as merchants, brokers, barristers, financiers, manufacturers of all kinds, pharmacists and the like. Chemistry is now so intertwined with almost all walks of life that probably every educated man at some time or other has wished to know something about a substance which he has found necessary for some purpose, and it is to such a class that the present book will appeal. He will here find a brief but clear account in non-technical language of almost every chemical substance that has attained any practical importance, with some of the principal constants inserted. Even professional chemists, who have access to exhaustive treatises on chemistry, will find the book handy for rapid reference, especially as it is clearly printed and attractively bound.

Some omissions are bound to occur in a work of this kind. For example, the well-known names "Westron" and "Westrosol" do not appear, although other preparations with a similar name and composition are mentioned. It would have been advisable to have stated that the basis of these non-inflammable solvents consists of chlorinated hydrocarbons, such as tetrachlorethane, trichlorethylene, and the like.

Studies of Scientific Development.

Isis: The International Review devoted to the History of Science and Civilisation. The official organ of the History of Science Society. Edited by Dr. George Sarton. (Weissenbruch and Co., 49 rue da Poinçon, Brussels.)

A FEW months back the formation of the History of Science Society, to carry on in a more permanent form the work which Dr. Sarton has been doing at the Carnegie Institution of Washington since the War, was announced in NATURE. The first volumes issued under these new auspices have just reached us and encourage the highest hopes as to the future of the enterprise. Estimated on the lowest basis, they are extraordinarily good value for the money, a subscription of five dollars covering the whole. Those who joined for this year will have already received two volumes, counting as Parts I., II., and III. of vol. 3. The first, besides various reviews, contains a longish article by Dr. Sarton himself, explaining under the title of the "New Humanism" the objects of the new association and its organ. It is, in fact, a programme and a confession of faith by the founder. The second is a full and very careful bibliography of all the books and articles which have been approved in the second half of 1923 on the history of science and philosophy and the history of civilisation. Its classification aims specially at bringing out the interdependence of the scientific development of different countries at the same time and thus illustrates the unity of mankind and the unity of knowledge.

The third part, however, is the review proper and contains this time a large number of articles interesting alike to the specialist and the general reader. Four languages are represented among the writers, six being English, three German, one Italian, while French occurs frequently, being the natural language of the editor and forming the bulk of his article on the Irish Walton, the aquiculturist of the middle of the thirteenth century.

Among many good things one may select two other articles for special comment. Both open up a rather unfrequented line of thought in Great Britain. The first is the "bio-bibliography" of Hunáyn Ibn Ighág, the distinguished Arabian medical savant of the ninth century. This is by Dr. Giuseppe Gabrieli, the librarian of the institute in Rome for the study of Mohammedan science; it is intended to be the first of a series of such lives, which are greatly to be welcomed at the present moment when the relations between East and West are in a state of critical tension. The other article which specially attracts us is that by Prof. Lynn Thorndike, the learned author of the recent history of magic a experimental science in the middle ages. He treats *Isis* of the history of science as it appears in the famo French Encyclopédie. He has studied the book ca fully from this point of view and the results are som what unexpected. The encyclopedists are far less fr from medieval prepossessions and errors than th thought themselves, or than posterity has suppose They are far less violent against theology. But th strongest line was the history of industry and t mechanical arts. This was Diderot's own departmer who was himself the son of a cutler. The article on t stocking knitting frame and its 2500 parts is ten tim as long as that on cathedrals! When we remember th this was in 1751, before the steam engine, it would see that we should regard Diderot as even more the proph of the Industrial, than of the French, Revolution.

F. S. M.

Cambridge Readings in the Literature of Science: bei Extracts from the Writings of Men of Science to illu trate the Development of Scientific Thought. Arrang by William Cecil Dampier Whetham, and his daught Margaret Dampier Whetham. Pp. xi + 275 + 8 plate (Cambridge: At the University Press, 1924.) 7s. 6 net.

IN these days many young students are apt to igno or belittle the intellectual and practical achievemen of bygone generations, and any book which deals in a interesting and accurate way with the stages th form landmarks in the development of science is t be commended. In the present work the authors ha shown excellent judgment in their choice of extrac from the literature of science, and the explanato introductions they have written to the extracts ad considerably to the value of the whole.

The book is divided into three sections, of which th first traces the development of men's views on th structure of the universe, beginning with Genesis an ending with Eddington on "Space, Time, and Gravita tion." In the section on the atomic theory are give extracts from Lucretius, Paracelsus, Dalton, Avogadr Mendeléeff, Faraday, Arrhenius, J. J. Thomson, Astor Moseley, and Rutherford, all of which appear to us t be particularly well chosen. The third section, dealin with evolution, contains, *inter alia*, selections from th writings of Aristotle, Lamarck, Lyell, Pasteur, Darwin Mendel, and T. H. Morgan; it concludes with a some what dogmatic passage from Bergson to the effect tha thought, being a product of evolution, will therefor never be able to grasp the true meaning of th evolutionary process. Some readers may demur to th inclusion of Bergson and the exclusion of Kant; other may think that quotations from Genesis, and specula tions of thinkers before the dawn of positive science are rather out of place in an anthology of the literature of *science*; but all will agree that the work as a whol has been excellently done, and that every student o science, whether in school or university, should b encouraged to read it and re-read it.

Social Science.

The Biological Foundations of Society. By Prof. Arthur Dendy. Pp. x+197+17 plates. (London: Constable and Co., Ltd., 1924.) 7*s.* 6*d.* net.

Population and the Social Problem. By J. Swinburne. Pp. 380. (London: G. Allen and Unwin, Ltd., 1924.) 15*s.* net.

THE student of social science may approach his task with either one of two objects in view. He may attempt to expose the permanent conditions upon which social evolution depends. He may, on the other hand, seek to deal with his material in much the same manner as systematists and morphologists have dealt with animals and plants. He may, in short, aim at the building up of a social morphology.

It is seldom denied that the adjective "scientific" is appropriate to studies of the first group. Under that heading falls the study, not of inheritance itself, but of the factors which are operating so as to produce changes in the germinal constitution of the race, and of factors which, given a knowledge of the conditions under which modifications are produced, can be detected in the process of impressing modifications upon each generation. Here also comes in the study of comparative psychology and the study of the manner in which the social heritage is built up, added to, passed on and lost: in other words, of the mechanism of the inheritance of tradition. The term scientific is, on the other hand, sometimes denied to studies which fall under the second heading. It is apparently held at times that they cannot be distinguished from historical studies which, by reason of the fact that they assume the form of a narrative and deal with the particular rather than with the general, are judged not to belong to science.

There are, however, grounds for distinguishing clearly between historical studies and scientific studies of social data. Not only may the latter, as also the former, be made with that detachment of outlook and accuracy in detail which characterises science, but also, in place of aiming at a narrative of particular events, they may aim at what Prof. Hobhouse calls a "descriptive synthesis." This may take the form of comparative social morphology, of the study of the trend of the evolution of an institution such as property, of an association such as the family, or of a particular civilisation. Between such studies, and those undertaken by systematists and morphologists in zoology and botany, it is hard to find any fundamental distinction, though it may be convenient to distinguish between "natural" and other sciences. The rate of progress in this field is slow, and while there may at times be grounds for the complaint raised by sociologists that their studies are not given the recognition which they deserve, it may not be out of place to remark that, if sociologists were to spend less time in discussing the scope of their science, what methods of investigation are appropriate, what the relation of sociology is to other sciences, and cognate questions, if in fact they were to get on with their task, recognition would come more quickly.

When workers in social science have firmly grounded and widely extended their studies, it may be some generations hence, a position may be reached not unlike that which faced Darwin when he surveyed the biological sciences in the middle of the last century. The systematists and morphologists had brought their studies to a point where the main outlines were clear and undisputed. It was then possible to apply to the facts so systematised what was known of the permanent conditions upon which organic life is based and to put forward a theory of evolution. So too in years to come, when enough preparatory work has been done, it may be possible to found a theory of social evolution which will show order and sequence in the data handled.

(1) The need of the time is for scientific research in both these directions. The temptation is to neglect spade work and to elaborate premature theories. It is here that Prof. Dendy's book is helpful. It may be described as a short and elementary course in general biology containing the minimum of biological knowledge that should be in the possession of all students of social science. Those who propose to pursue any branch of social science which falls under the first of the two divisions mentioned above will of course require far more detailed biological knowledge than this book can give. It will be to those whose interests and work lie in the other field that this book will be useful.

It is possible to do valuable work in systematic zoology and botany and to be almost entirely ignorant of general biology. But quite apart from the interest which a knowledge of general biology adds to these studies, such knowledge has a value in that it directs the worker's attention to many facts which he might otherwise neglect as unimportant but which, if recorded, may illuminate general biological problems. So too in studies of social data, some knowledge of general biology is not only interesting but also of great value. Had all those, for example, who have collected facts regarding existing primitive races had some grasp of biological problems, how much might they not have assisted indirectly in solving those problems by amassing data bearing upon them which, in the absence of biological knowledge, seem wholly unimportant? Or again, if attendance at a course in elementary biology was compulsory for those who are going to pursue that branch of social science known as economics, how much more definite and concrete would be their knowledge of the human material with which they deal. Prof.

Dendy's excellent little book deserves a wide audience among students of the various branches of social science.

(2) It is possible to study the population problem by attempting to lay bare the permanent conditions upon which it rests, or by collecting the facts regarding the control, density, or some other aspect of the problem under different conditions and then attempting to ascertain the trend of social development in whatever field is chosen. Mr. Swinburne's book is a disappointment in that, while written by a scientific man, it is not a scientific treatment of this problem in social science. From the book we learn what opinions Mr. Swinburne holds and what prejudices he harbours regarding most social questions of the day, including, for example, the relations between capital and labour, profit-sharing, the rights of man, government, the position of women, trade unions and socialism.

The connexion of all this with population is obscure, but those who disagree with Mr. Swinburne are asserted to hold erroneous views about population, though why they are erroneous, and what Mr. Swinburne's own views may be, are nowhere in the book logically and consistently set out. His reference to economists and their treatment of the population will serve as an example of his tone and style. "The curious point about economists' treatment of the population principle is that they never seriously discuss it or try to refute it." It is only necessary to recall that the fourth volume of the new Cambridge series of economic handbooks is wholly devoted to the population problem, and that a discussion begun by Sir William Beveridge at the Liverpool meeting of the British Association, and continued by Dr. Keynes and other well-known economists, has been occupying a very large amount of attention for more than a year in order to see the value of Mr. Swinburne's statements. All this work is entirely neglected by Mr. Swinburne. Can he have written a book of nearly 400 pages on population in ignorance of it, or, as the following quotations suggest, does he hold so low a view of the intelligence of economists that he does not read their works?

"There is no proper opening for economists, and no adequate inducement for men of first-rate ability to devote themselves to the study. The highest pinnacle an economist can reach is a professorship at some university or college. He may also write a text-book or two and there his career ends. . . . Generally speaking, an able man who can do anything else well has a strong temptation to leave political economy alone. . . . A man who might be a first-rate economist can do nearly as well in many other directions that give more return, and naturally he does so."

Whichever explanation is correct, the conclusion would seem to be that only those who are interested in Mr. Swinburne's prejudices will profit by reading his book.

A. M. C.-S.

India, and its Problems.

India: a Bird's-Eye View. By the Earl of Ronaldshay. Pp. xiii + 322 + 24 plates. (London, Bombay and Sydney: Constable and Co., Ltd., 1924.) 18s. net.

THE Indian Continent is such a vast agglomeration of different languages, different religions, and different peoples, not to mention varieties of climate and topography, that it is no easy matter to present it in a single view without a tendency to confuse and bewilder the reader who is not familiar with the various problems concerned. But Lord Ronaldshay is an experienced administrator who has had opportunities, on the staff of a Viceroy and later as the Governor of a great Indian province, not often enjoyed by those who have an inclination to write, and at the same time possess the pen of a ready writer. Further, he has devoted much time to the study of the history, religions, and archæology of India, in the course of which he has travelled much and has had personal experience of the scenes he describes so well. His position has necessarily brought him into contact with all that is best of modern India both in literary and political circles; so he is peculiarly well equipped to give a general sketch of the country, and in this he has acquitted himself as well as a difficult task permits.

In a chapter on "What the Buildings tell" the reader is introduced to the immense variety of architecture displayed in "the edifices raised over a vast span of time to the known and unknown gods of Indian belief," and the question is asked, Whence came the people who could produce such contrasts?

Thus we are led to the great gateways, on the North West Frontier, in the mountain wall which hedges in and separates India from the rest of Asia, through which successive waves of invaders have passed, penetrating southward and eastward, bringing those Aryan races which have become the most numerous element. But one thing leads to another, so a description of the North-West Frontier, and its people, leads on to the ever-recurring problems connected with this troublesome corner of the Empire, especially those difficulties which have arisen owing to the no man's land existing between the British Administrative Frontier and Afghanistan. The story of our relations with the frontier tribes in recent years is told, and how, in spite of all our desires to the contrary, a forward policy has been forced upon us as the result of the climax brought about by the third Afghan War. We have now had to adopt a policy of permanent occupation in Waziristan, that is, provided the policy remains permanent, an important proviso. It may be ex-

sive, but, probably, less so than the policy of ated punitive expeditions, followed by withdrawal, ch, under present-day conditions, requires an ever- easing number of men to cope with the better ed, and better trained, tribesmen. Permanent cupation will go far to remove the economic causes nrest on the Frontier, which lie at the root of most ur difficulties. We shall also be the better able to otrol those outside influences which have done so ch harm in the past. Lord Ronaldshay's chapters the Indian Frontier problems will do much to ghten those who want to understand what these blems really are.

rom the incursions from Central Asia the author s to the last incursion which reached India by sea m the west. He gives a sketch of the well-known ty of the rivalry among European nations, first for possession of the trade of the East, ultimately for possession of India itself, and the final victory of British. As a typical example of operations in hese early days he describes, in some detail, the battle ofPlassey and a personal visit to the site which he ade a few years ago.

n view of the present-day controversies which surround questions of the form of representative govern- ment best suited to India, all that Lord Ronaldshay has to say on the subject, in the two chapters on "Local Self-Government" and "The Indian Village," is of importance. Because we possess in a high degree the art of managing our municipal affairs by means of elective councils, it does not follow that such methods are suitable to the Indian soil. The author gives numbers of instances of failure of the elective principle. With the advent of the British, Western methods were forced on a people whose ideas of government are radically different from ours. If our methods are to succeed it will only be after a long course of instruction, and, as it were, acclimatisation. But we are not pessimistic as to the future of India, for we believe the British have an innate genius for overcoming these kind of difficulties, and finding a way out, though it may take time. One has a feeling that, on this subject, the author does not express himself as freely as he would like.

Two chapters are devoted to "Industrialism of the West" and "Wealth and Actual Potential." Like Western government, Western industrialism is distaste- ful to Indian ideas, and politicians have not been slow to make use of this fact. In England 80 per cent. of the population is urban, while in India 90 per cent. is rural, engaged in agricultural and pastoral pursuits. As a rule the Indian does not take kindly to factory life in the great industrial centres—his thoughts are in his village, to which he returns at the first opportunity. His heart is not in his occupation, and he often makes an inefficient workman. As a consequence, though wages are lower, a larger number of men are employed to produce a given article than in Europe, which often results in the Indian production being more costly than that which could be imported. The Indian politician, even Mr. Gandhi himself, though inveighing against modern innovations, is not above making use of rail- ways and motor cars. Gandhi has made a dead set against European medicine, "which has been singled out for special attack," but by a curious irony he has recently undergone a serious operation at the hands of a skilful English surgeon who saved his life. One cannot help thinking this antagonistic attitude towards industrialism has more of a political motive than anything else, certainly among the extremists, merely because of its Western origin. In India one often hears the development of Japan applauded as an example of what an Eastern people is capable of achieving.

British future commercial relations with India must be free from the suspicion that we have any desire to exploit her. The author puts this point very well when he says: "It must be for the good of India that her wealth should be increased, and since outside aid is necessary to this end, what has to be done is to make it clear to India that the aid which Great Britain can offer her is given to the mutual advantage of the two countries, that if British business men look to receive a reasonable return themselves, they have no desire to deprive her of a reasonable share of the total profit. In other words, what they desire to do is not to exploit her to her disadvantage, but to co-operate with her in a business of mutual benefit."

Popular Hinduism is dealt with in a chapter de- scribing some of those great religious festivals which play such an important part in Indian life, many of which the author has personally witnessed. When one considers the original meaning, and sublime concep- tions, which have been read into some of these cere- monies, one is astonished at the wide departure from the original one sees to-day. It is not difficult to imagine the sceptic asking whether poets and thinkers in trying to explain away, by dint of allegorical inter- pretation, certain ceremonies, are not making ingenious attempts, though perhaps unconsciously, to put a fair complexion on practices which are not in accordance with modern ideas.

The concluding portions of the book endeavour to explain the reasons for the pessimistic outlook on life which apparently pervades the majority of Indians. This is attributed, partly to climatic and physical surroundings, which have enervated and saturated the people with malaria, and partly to the hopeless

religious doctrine of *Karma*, which lands those who believe in it in a tangled maze. The consequence of this doctrine, to the believer, is that "all existence in this world is suffering and sorrow"; the Hindu's ambition is not to prolong it but to escape from it. In these circumstances how can life be anything but a joyless existence? We are told of the measures which have been, and are being, taken to combat the evil of malaria, a most difficult matter when such a large area is concerned. These are based on the discoveries of Sir Ronald Ross and others, and are being carried out on a large scale, with ultimate benefit to the people.

Lord Ronaldshay always wants to get to the origin of things, and this adds enormously to the interest of what he has to say. Some of his pen pictures are delightful, as where he describes dawn on the Frontier; they vividly recall the scenes with which the Anglo-Indian is familiar.

It has not been possible to do more than touch on some of the topics with which this book deals. We thoroughly recommend it to all who would know about India; it is written in a pleasant style and is the result of much study and experience acquired on the spot. The reader will find something of interest on almost every page. H. L. C.

The Ascent of Man.

Making of Man: a Study in Evolution. By Sir Oliver Lodge. Pp. 185. (London: Hodder and Stoughton, Ltd., 1924.) 3*s.* 6*d.* net.

SIR OLIVER LODGE is unique among our men of science in commanding public attention on general and religious questions, as well as on the branch of science which he has made his own. Hence the little book before us will have a large audience, rather for its qualities of inspiration and feeling than for any definite contribution to its special subject. For on the biological side it is extremely scanty, and compares curiously in this respect with the volume of somewhat similar size and title from Prof. J. Arthur Thomson which we noticed a few months ago. The latter was from the pen of a biologist, this of a physicist, who has adopted with passionate conviction some highly speculative theories on psychical phenomena. But the book shows how perfectly Sir Oliver has learnt to use his great power of clear and simple exposition in the service of the religious propaganda which has now become the main interest of his life. The language is always effective and moving, though the sentiments are often obvious enough, and where he draws on his own province of physics, the illustrations are extraordinarily apt and sometimes beautiful. The conclu ing analogy of the Sun and the Divine is one of the b things of the kind we have ever seen.

But it is only fair to point out to intending read that they must not expect a scientific treatise. For t shortest summary of the biological or sociologi evolution of man, they must look elsewhere, *e.g.* to t little book by Prof. J. Arthur Thomson. Here we ha rather a series of sermonettes, variations on the the that the human spirit is an emanation of the Divi that we may trace in its history clear evidence of upward movement, that this movement is the result continued effort, and that we can only attain a bel in "rational optimism," in the divine governance the world for good, by seeing in this "effort" t necessary condition of any movement. It is here th Sir Oliver's physical analogies are most to the poi He shows in an early chapter how all change in mo ment involves force, and how all force implies resistan This leads to the argument that evil is, philosophica considered, only the reaction implied in action. Thi are not "done easily by nod, even by the Deity."

As the book thus becomes within its limits rathe philosophical, religious treatise than a scientific wo one would like to see some of these philosophical c ceptions more deeply penetrated. But even this se of insufficiency does not prevent a real outburst gratitude and admiration for the veteran thinker a writer, who thus in the evening of his life puts forth su an inspiring exposition of his beliefs on the deep personal questions which move us all; and, though shows his own convictions on psychical phenomena frequent reference to "the other side," he does r allow this prepossession to disturb the general ar ment. Men of all views, in fact, can find something their advantage in the "Making of Man."

F. S. MARVIN.

Prehistoric Times.

Ancient Hunters and their Modern Representatives. Prof. W. J. Sollas. Third edition. Pp. xxxvi+6 (London: Macmillan and Co., Ltd., 1924.) 25*s.* n

IT is nine years since the second edition of Pr Sollas's "Ancient Hunters" appeared. T present book, although substantially the same structure as the last, has been revised and brou up-to-date. New matter has been added involvi the lengthening of the work by more than a hundr pages and the addition of several illustrations. I rapidly developing subject like prehistory it is i possible to say that the last word has been written, b it can safely be prophesied that, in this revised a up-to-date form, "Ancient Hunters" will be for ma

ers to come an essential feature on every specialist's ckshelf, and will remain the best book to recommend o the thoughtful non-specialist reader interested in h subject.

As in the previous editions, the work opens with two apters on quaternary geology and the antiquity of an. There follows a discussion of the thorny eolithic oblem, where Prof. Sollas very judiciously sits on the nce, and next a description of the various Palæolithic ultures (here, perhaps, the specialist will regret the mission of the term Middle Palæolithic for Mous-erian) interdigitated with accounts of what Prof. Sollas considers to be their modern counterparts—the Tasmanians, Australians, Bushmen, and Eskimos. The book concludes with a résumé of our knowledge of the chronology of Palæolithic times.

As regards the chapters on modern primitive peoples, while these are very illuminating to the specialist, perhaps a word of warning may be forgiven for the sake of the casual reader. Similar climatic conditions do undoubt produce a certain similarity of cultures when acting on more or less automatic humanity, but this must not be carried too far. Similar flint implements do not postulate similar ceremonies and modes of life. In the case of the Tasmanians and Australians, it seems positively dangerous to link those cultures in any way with that of early Palæolithic man in Europe, merely on the strength of there being a certain similarity in their stone tools. Although Mousterian culture apparently occurs in quaternary deposits in northern China, linked to that of western Europe by finds in southern Siberia and eastern Europe, it is a far cry from the prehistoric industries of northern China to those of the more or less modern inhabitants of Australasia. The same may be said of the Eskimos, though in this case a similarity in skull form has been adduced. With the Bushmen of South Africa, however, we are on safer ground. Not only are the tools similar but also the art—a much more conclusive criterion—is in some cases almost identical; compare the finds at the Barranco de Valltorta in east Spain with some of the Bushmen paintings—the technique is the same. Again, the Bushmen have a legend that they came from the north, and therefore probably from the same stock which supplied Neoanthropic man to western Europe.

In conclusion, one can have nothing but praise for this excellent third edition, the popularity of the predecessors of which has borne testimony to its worth. Prof. Sollas writes from first-hand information, having taken the trouble to visit personally the sites of discoveries so new that they had to be put in an addendum note at the beginning of the book. It is an open secret, that on receipt of a chance card, he posted without pause to the south of France and waded up to his waist in ice-cold water to see these new finds at Montespan. May this fascinatingly readable book, readable though information or material is never sacrificed to make it so, have the great success it undoubtedly deserves. M. C. B.

The Problem of Atlantis. By Lewis Spence. Pp. xi + 232 + 16 plates. (London: W. Rider and Son, Ltd., 1924.) 10*s.* 6*d.* net.

THE Atlantis problem affects so many departments of scientific inquiry that it is always with us. Mr. Lewis Spence, author of a series of books on the folk-lore of America and Egypt, is an enthusiastic champion of the existence of Atlantis, and of the historic importance of the Atlanteans. In this volume he conveniently collects the classical traditions on the subject and evidence from geology, biological distribution, archæology, and folk-lore, of a former connexion between Central America and the Mediterranean region by a transatlantic land.

There is much geological and biological evidence in favour of the existence of this land in the early and middle Kainozoic—a period, however, long before the age of man; but it gives no direct proof of large islands in the mid-Atlantic at the time required by the Atlantis theory. The direct land connexion between southern Europe and the opposite coasts of America must have been broken at the end of the Miocene; but there may have been surviving islands which have gradually foundered, just as Malta is a fragment of a land that once connected North Africa and Sicily, and has been reduced in size by repeated subsidences. If the rest were submerged, some ingenious critic might claim that the reports of Malta and its Phœnician population and its Knights of St. John were all an allegorical myth; and neither the geologist nor the biologist could refute him.

Atlantis may have been the remnant of a mid-Atlantic land which was inhabited by a cultured race that sent colonies into both the Old World and the New. The author claims that the Cro-Magnon race came from Atlantis and entered Europe from the west—a conclusion which would remove some difficulties. The direct evidence of the survival of Atlantis into the human period depends on the archæological evidence. Mr. Spence shows that the amount in common between Central America and Peru and the Mediterranean region is far more than can be explained by coincidence. He agrees, therefore, with Prof. Elliot Smith that the cultures of Egypt and tropical America were indebted to the same source; but he rejects the view that the connexion was established across the Pacific, owing to the absence of evidence of the Asiatic influences that should have been engrafted on the culture if it had passed from Egypt to America by

an eastward route. Mr. Spence recognises that the people of south-eastern Asia influenced those of tropical America; but he regards this connexion as independent.

The author is indiscriminate in his acceptance of anything that appears to support his views. Many of his arguments are unconvincing, such as the identity of the names Cleito with Coatlicue and of Atlas with Uitzilopochtli. He also accepts newspaper statements, which, though often useful as a clue, are not scientific evidence. Thus he remarks that the discovery in August of last year of a 2¼ mile rise in the floor of the South Atlantic in the course of the previous twenty-five years should make "the scoffer" revise his belief in the stability of the ocean beds; but the author's acceptance of this "mare's nest" may tend to make his readers scoff at a theory which accepts such statements without troubling to confirm them or even awaiting their contradiction.

L'Homme préhistorique dans l'Europe centrale: *Primeval Man in Central Europe*. By Prof. Dr. P. Goessler. Pp. 134 + 40 plates. (Stuttgart: Franckh'sche Verlagshandlung, 1924.) n.p.

In this volume Prof. Goessler, Director of the State Museum of Antiquities in Stuttgart, has published a series of forty plates with descriptive letterpress, each dealing with a type of prehistoric man or of prehistoric culture, the type skull being figured with characteristic associated implements, ornaments, etc. The series begins with Heidelberg man and ends with the races of Central Europe of the present day. Students will appreciate the special attention which is given to the archæology of south-east Germany. The author has not, however, confined himself to Central Europe, and in the palæolithic age in particular the skeletal remains of early man from France and Britain as well as Rhodesian man are duly noted; but Piltdown man obtains no more than an incidental mention in connexion with the Galley Hill skull. In later periods, especially the bronze and iron ages, while the place of origin of German finds is, for the most part, carefully noted, in the case of many of the objects figured from other sources, this information is not given at all or only vaguely. The text is in German, French, and English, but the last-named is so bad as to be unintelligible at times without the original German, and shows almost complete ignorance of English technical nomenclature.

Man before History: *a Short Account of Prehistoric Times*. By Mary E. Boyle. Pp. 128+8 plates. (London, Calcutta and Sydney: G. G. Harrap and Co., Ltd., 1924.) 2*s*.

Of the total number of pages in Miss Boyle's little book, one hundred deal with the palæolithic period proper. The remaining 28 pages cover the Azilian, the Neolithic, the lake villages, the arts and crafts of the neolithic age, and the beginning of writing. This may seem a little out of proportion, but as her book is written for young people, her scale of treatment may be regarded as justifiable, especially as in t comparatively restricted space she has been able indicate, at any rate in outline, the more promine characteristics of the culture of the later period. S has wisely paid particular attention to the art of p historic man. Indeed, there is no book of this si and type which contains so many excellent reprodu tions of the cave paintings and the carvings as ha been given by Miss Boyle. The later and less we known art of Spain also receives due attention. M Boyle tells her story in a straightforward mann which is very much to the point. Within its lim this is an admirable little book and one of the be of its kind.

The Evolution of Man: Essays. By Dr. G. Elli Smith. Pp. viii+159. (London: Oxford Unive sity Press, 1924.) 8*s*. 6*d*. net.

In this volume Prof. Elliot Smith has reprinted thr addresses—his presidential address to Section H at t Dundee meeting of the British Association in 1912, paper presented to the British Academy in 1916, and lecture delivered at the Royal Institution in the curre year. Each deals with some one aspect of ma evolution, with particular reference to the specifica human attributes which evolve *pari passu* with t development of the brain. To them he has added foreword in which he demonstrates with diagrams tentative scheme of the relationships of the differe genera, species, and races of the human family and similar scheme of the relationship of the order of p mates. In the former of these he puts forward wh are undoubtedly very suggestive views on the proble presented by Eoanthropus and Rhodesian man. Pr Elliot Smith has republished these lectures to meet t need for a consistent and coherent account of t essential factors in the evolution of man, pending t preparation of a more elaborate text-book, which, it needless to say, will be heartily welcomed by all who a interested in this subject.

Origins in Place Names. By An Ignorant Stude VI.: *Life*. Pp. 7. (London: Privately printed the Chiswick Press, 1924.) n.p.

Although numbered the sixth in the series, this is t fourth in order of publication of the pamphlets which "An Ignorant Student" discusses the origin place-names from various aspects. In this case l object is to link up place-names with the order universal law by showing that they evolve logical from a conception of life as functional and the resu of an arrangement and grouping of individual uni Just as from the leaf of a tree certain deductions can drawn, it is possible to deduce from language, which an expression of life, the country in which it grew and, careful analysis, to arrive at the elements of which it composed. The author's conclusion, therefore, is th among the earliest forms of language were the word which we now call place-names, describing and locati the homes of the people who used them. This, somewhat obvious, is no doubt true, provided a reserv tion is made in favour of the priority of certain oth classes of words dealing with the personality a primary needs, such as food.

The Galapagos Archipelago.

lapagos: World's End. By William Beebe. (Published under the auspices of the New York Zoological Society.) Pp. xxi+443+65 plates (9 coloured). New York and London: G. P. Putnam's Sons, 1924.) 42*s.* net.

THE Galapagos Islands are situated directly on the equator, about 500 miles distant from Ecuador, which claims their sovereignty. They are volcanic islands, arising precipitously from a bank at 2000 metres, and their topographical connexion is with Costa Rica and Panama, 650 miles distant, with the lonely Cocos island between. They number 13 larger islands with numerous coastal islets, the largest island (Albemarle) more than 70 miles long, and they were formerly described as having 2000 craters. They are all volcanic, and every few years there are outbursts in one or other of them. Unfortunately they have no water, except what accumulates in pools in a short rainy season, so that the vegetation is relatively scant, except in selected spots, without that accumulation of broken-down rock and plant remains, which forms the rich soil of most tropical islands. Their shores are rocky in the extreme with cliffs and great boulders, and small inlets here and there, the sort of shore one is accustomed to expect on oceanic islands formed by submarine volcanic activity after the ash is washed away and the lava laid bare. Their surface is jagged rock with bushes and cacti in the crevices, so inexpressibly uncomfortable and thirsty that the interior of the larger islands would seem never to have been explored.

"A land pitted by countless craters and heaped into a myriad mounds of fragmentary rock; gnarled trees bleached by salt spray, with twisted, stunted branches; grotesque cactus stiffly outlined against black lava boulders . . ."

First the scene of the legendary adventure of an Inca king, then in 1535 explored for spices and gold by a Spanish bishop, later for almost 200 years the refitting station of buccaneers and whalers in succession, the Galapagos may now be described as almost a holiday resort for scientific expeditions. Chatham island alone was inhabited as a penal and cattle station, the others almost untouched save for the ravages of pigs, goats, cattle, donkeys, and dogs on different islands. Dampier, that great exploring buccaneer, Porter, a raider on peaceful whalers, Darwin, a young ship's surgeon of twenty-six, and others, described them in terms which are generally correct to-day, so small are the changes produced by man.

The Californian Academy of Sciences, in an expedition under R. H. Beck in 1905, collected for almost a year and secured specimens of all sorts in such vast numbers that further collecting would seem unnecessary. However, in 1923 the New York Zoological Society adventured through one of its patrons, Harrison Williams, who took a party on board his yacht for a three weeks' cruise there. Beebe, one of the soundest of the United States naturalists and a most enthusiastic observer, was in charge, having W. M. Wheeler as entomologist and a party of twelve more including curators, artist, photographers, historian, preparateur, physician, and taxidermist. The object was clearly to get living animals for the Society, exhibition specimens for the Museum of Natural History at New York, and films and photographs of wild beasts, that still have no fear of man, for the general public. It was simply a scientific reconnaissance, extraordinary only in the quality and completeness of its personnel and equipment, and in these respects it may be described as "the last word." The immediate result is a readable book by Beebe, full of interesting observations, while Osborn contributes as florid an introduction, "In the Wake of Darwin," as we ever remember to have seen outside journalese, describing the expedition as "among the scientific wonders of our century"; "It is like rubbing the Aladdin's lamp of science," etc., terms which we would ourselves prefer to apply rather to the wonderful series of American palæontological results to which that author has himself been such an inspiring contributor.

Space permits reference to only a few of the natural history observations. We particularly like the accounts of the sea iguanas, up to 4 feet in length, in their vast numbers on suitable rocks, swimming by their flattened tails with hanging-down legs by which they cling for browsing on the seaweeds in the foam of the breaking waves and by which they drag themselves on land; the description of a crab crawling over one and picking off its ticks would not be believed if described by any other observer than Beebe. The mocking birds (Nesomimus), their habits and distribution, are scientifically interesting, once continental visitors, now perhaps species in the making in the different islets. A small penguin occurs, the only example north of the equator, and then there is the flightless cormorant, a bird one third longer with its wings 40 per cent. shorter than its nearest allies, as wonderful in many ways as the classic great auk, and like it, assuredly, doomed to disappear.

The huge southern sea-lions were generally so tame that the naturalists could approach and pick up their babies at will, their chief foes and those of the seals being rather of the water than of the land. Buccaneers and whalers came to the islands largely for the giant land tortoises, and the Californian Academy Expedition collected more than 250 specimens in which they recognised 15 species, separated from one another chiefly

on shape, with no real structural differences. They are known from 11 islands, each of which had one race, with the exception of Albemarle, which had several. All the evidence points to no interchange of tortoises between the islands, and the problem here, as in the Mascarene islands, is the method of their arrival, the evidence of any continuous land mass for their transport being equally small. Beebe only took one, and that from the bottom of a crater on Duncan Island; he found that it swam well and intelligently, this being against his views as to the necessity of a former land connexion with Costa Rica to explain the flora and fauna now existing in the Galapagos. At Albemarle they used to occur on the highest mountains, where there is much rank grass. A Guayaquil farmer started here a ranch to round up the cattle for their hides while the old tortoises were killed for their oil, few young, if any, surviving the depredations of the dogs. Whether any still exist in Albemarle is doubtful, and anyhow, unless there is some reservation, they will soon be known only as beasts of a past age. This is the fate which has befallen the land iguana on most islands, but Beebe found them still numerous in South Seymour. These lizards attained a length of 50 inches and live inland in holes which they scratch in the ground. They are vegetable feeders, their epicures selecting buttercup flowers and their gluttons cactus fruits and leaves with their spines and all, the former shaken down like apples from a tree. In fighting, unlike most large lizards, they use their jaws rather than lateral swishing movements of their bodies.

There is much else in Beebe's book to which we would like to refer: the finding of six bleached skeletons of the rare killer whale (Pseudorca), the capture of a species of Branchipus, many notes on the habits of birds, insects, and crabs, and a whole chapter on the life in rock pools. The impression we have gained is that, while there is no use for any more exploring expeditions, the Galapagos is still an immense field for the naturalist in the study of the mode of life and of the life histories of all the more lowly land forms. In particular, from a species point of view, the insects scarcely seem to have been touched, and a collector of the type of Perkins or Scott might find as rich a fauna as these two found respectively in Hawaii and Seychelles. We suggest to the New York Zoological Society that all speculation as to the origin of the Galapagos fauna is vain in the absence of such an intensive study, and that the outcome of their reconnaissance should be a determined attack directed to this end, before the islands are altered still more by the animals man has introduced. This, we conceive, is what the progress of biological science demands from them.

J. Stanley Gardiner.

Animate Nature.

Animal Studies. By James A. Todd. (Foundati of Nature Study Series.) Pp. 135. (Edinburg A. Baxendine and Sons, 1924.) 2*s.* 6*d.* net.

With the best intentions in the world it is impossi to give an adequate summary of the animal kingd in ninety small pages of print, and the author of t little book has attempted too much in the spa allowed him. The book has been published mainly obviate the so-called waste of time involved in no taking by students. The author's own lectures m of necessity have been fuller than the very imperf summary given here would indicate, and judicic notes taken by the students themselves at the ti would have been infinitely more useful to them. T book is an example of that tendency to excessi spoonfeeding which is so much to be deprecated modern educational methods, and can serve no rea useful purpose. The illustrations are poor and in ma cases unrecognisable. We have not detected ma actual errors of fact, but Asellus is not found on t seashore, and the generic name of the blow-fly is correctly given.

Vivarium and Aquarium Keeping for Amateurs: Practical Guide to the Hobby. By A. E. Hodge. P 128+6 plates. (London: H. F. and G. Witherb 1924.) 5*s.* net.

As the author justly remarks, the construction vivaria and aquaria is mainly a matter of comm sense and ingenuity, based on an adequate knowled of the habits of the animals to be kept in the Mr. Hodge is, therefore, content to lay down a f guiding principles and to devote the main part of t book to those special requirements of food and enviro ment peculiar to individual species, the knowledge which is only gained by experience. In this respe the book is most valuable, and the author's hints a practical advice will save the beginner many an anxio hour and many an unnecessary loss. Attention confined to reptiles, batrachians, and fishes, with speci reference to the British species, and only to those whi require no heating apparatus. The book makes timely appearance in view of the opening of the ne aquarium at the London Zoo, and should do much popularise a fascinating hobby.

Deer-stalking in Scotland. By Alexander Inks McConnochie. Pp. 208+8 plates. (London: H. and G. Witherby, 1924.) 10*s.* 6*d.* net.

The author has here collected together a series memories and adventures among the deer forests Scotland, contributed by enthusiastic devotees of t sport of deer-stalking, and a goodly number of stalki yarns wherewith to beguile the autumn evenings aft a good day on the moors. The book is essential written for the sportsman rather than the naturalis The chronicle is well and racily told, and will appeal all those who have experienced the thrill of the hun The Duke of Atholl contributes a preface, in which h touches briefly on the much-disputed question of th economics of deer forests.

Thermionic Valves and Radio Communication.

Thermionic Valve and its Developments in Radio-telegraphy and Telephony. By Prof. J. A. Fleming. Second edition, fully revised. Pp. xiii + 438. (London: The Wireless Press, Ltd.; New York: Wireless Press, Inc., 1924.) 15*s.*

So rapid have been the advances made in radiotelegraphy and radiotelephony that the author has found it necessary to rewrite much of the first edition of this useful book. The invention of the two-electrode thermionic valve by Prof. Fleming in 1904 made an entirely new departure in the radio art. The subsequent development of the hard three-electrode valve marks an equally important advance. With the exception of the crystal detector, all other types of detector for electric waves have now been made antiquated. As a generator of electric oscillations the valve has come to the front. As a relay or repeater in telephony also it is being very widely used. The author has added a new chapter on thermionic relays. A telephone line filter is described, and a clear account is given of carrier wave telephony applied to ordinary telephone lines. Speech has been transmitted perfectly from the Atlantic to the Pacific Ocean. It first passed by radio thirty miles over the sea, then 4000 miles overland by wire, and finally it passed thirty miles over sea again by radio. All the transmissions were effected by thermionic valves, no human agency being employed.

Thermionic Tubes in Radio Telegraphy and Telephony. By John Scott-Taggart. Second edition. Pp. xxiv + 470. (London: The Wireless Press, Ltd.; New York: Wireless Press, Inc., 1924.) 15*s.*

The thermionic valve has come into almost universal use for radio-communication. This volume describes the development of this valve and gives many of its applications. The author has considerable practical experience of valves and has made a judicious selection from the leading papers and the more important patents on the subject. If he errs at all, it is in making the book too comprehensive and going too much into detail. A beginner reading this book almost wants some one to point out what to read and what to omit, at least, on a first reading. Very properly the author begins by describing the phenomena in terms of modern theory. But we are afraid that our imagination fails to grasp what is meant by saying that there are about 10^{22} free electrons in a cubic centimetre of cold metal. Current is taken as flowing from points of high negative potential to points of low negative potential. Modern theory certainly explains very satisfactorily the working of the three-electrode thermionic valve. We can recommend this book to serious students of the subject.

Wireless Possibilities. By Prof. A. M. Low. Pp. 77. (London: Kegan Paul and Co., Ltd., 1924.) 2*s.* 6*d.* net.

It is useful occasionally to try to unravel the future. This is usually left to poets. The author of this little book, however, encouraged doubtless by the marvellous linking up of the whole world by radio-communication, has ventured to indicate some of the lines along which future developments will probably take place. Incidentally the reader learns many useful scientific facts. Radio television has almost been realised. Why not methods of preventing local thunderstorms and of improving the growth of wheat or of young animals? Radio waves may affect our health. Why should we not try to render this effect beneficial? The days of the outside aerial are limited. The study of radio-active materials may in one day produce the cold-emitter valve. It is difficult to believe that we are not on the eve of great scientific developments.

Forthcoming Books of Science.

Agriculture, Forestry, and Horticulture.

Coal and Electric Power.

A STRONG plea for an improved utilisation of coal as a source of motive power is made in the second part of the volume "Coal and Power,"[1] the Report of an Enquiry presided over by the Rt. Hon. D. Lloyd George, the first part of which has been referred to already in these columns (August 23, p. 265). The Committee of Liberal Members of Parliament and other persons responsible for the Report has examined the present system of generation and distribution of electrical power in Great Britain, and has come to the conclusion that "immense saving and improvement can be effected in this respect."

The waste that occurs in the methods now in vogue in connexion with the utilisation of coal for industrial and other purposes is a subject which has been under close study on the part of engineers in Great Britain, as well as in other parts of the world, for several decades past; the measures by which this waste can to some extent be reduced have been repeatedly indicated by them. The subjects of coal conservation, home-grown food, and the better utilisation of our labour were, for example, chosen for the theme of the able and brilliant presidential address which Mr. S. Z. de Ferranti delivered on November 10, 1910, to the Institution of Electrical Engineers (see Jour. I.E.E., 1911, vol. 46). In this address, Mr. de Ferranti directed attention to many of the matters which are dealt with, under the title "Power," in the Report before us, and pointed clearly to the direction in which a reduction in the cost of production of electrical energy should be sought, indicating, at the same time, that the increased use of electricity was a matter that depended almost entirely on the cheapness at which it could be sold. In view of the slow progress which has been made in Great Britain in extending the use of electricity for industrial and domestic purposes, and for the reason that important benefits would follow on its extended use, it is all to the good that the Committee should, in its Report, have again directed attention to the advantages to be gained from the electrification of our industries and our homes.

The Committee points out that the reorganisation of the coal-mining industry which it is advocating, though a matter of the utmost importance, is only part of a programme which aims at the rejuvenation of British industry, and it frankly admits that it is seeking the solution to the problem of how to increase wages without at the same time increasing the cost of manufactured commodities. The Committee shows that there is nothing incompatible in aiming at attaining

[1] Pp. xiv + 139 + 16 plates. (London: Hodder and Stoughton, Ltd., 1924.) 1s. net.

both these ends simultaneously. "A survey of the chief industrial countries of the world reveals," says the Report, "the extremely significant fact that those people are best paid and most prosperous that make most use of the resources of science"; the reason for this state of things being found in the fact that the average level of earnings must depend on production, and production increases as the use of power per head of the population increases.

Attention is directed in the Report to the circumstance that Great Britain became, in the first half of the nineteenth century, pre-eminent in the world as the greatest of all manufacturing countries because it was the first country in the world to realise the potential powers of steam. British engineers led all other countries; and, in the matter of railways, our system was the pioneer one. In the early days of steam engineering it was Great Britain that other countries copied: but now, in the matter of electrical development, the rôles are reversed. The Committee alludes to the activities of other countries which are our competitors in the world's markets, and mentions the fact that most of them are pressing ahead with schemes of electrification. "When one surveys the modern industrial world from this angle, it almost seems," says the Report, "as though we alone are content to mark time." An authoritative estimate indicates that the increase in the production of electricity in Great Britain during the period 1913 to 1922 was 130 per cent., an increase which is less than that achieved in any of the countries of our chief competitors. Again, whilst the development in Great Britain has hitherto been almost entirely in the direction of adding units to existing small and scattered local supply stations operating independently each of the others, foreign countries have in recent times been concentrating on larger power supplies on modern methods linked up and co-ordinated by main transmission lines.

A brief examination is made in the Report of the electrical development in certain foreign countries. This examination discloses the fact that the United States of America leads the way, its output having quadrupled since 1912; Chicago alone produces five times as much electricity as the whole of the North-East Coast plant, the largest scheme of electrification in England. The output in France had, up to April 1924, increased more than three and a half times as compared with 1913; the network of transmission lines is now so widespread that the ordinary hydro-electric stations are linked up with the glacier stations, and both with the thermic stations, and all with the consumers in the industrial region. It is expected that, by 1927, sixty-nine per cent. of the population will have electricity available. Germany, though harassed by many adverse factors, has made a greater adva in the direction of electrical development along c saving lines than has Great Britain; its output more than doubled since 1913. Lignite, a mineral very poor qualities, is now supplying nearly one-h of the electrical power of Germany.

In Holland, production more than doubled betw 1913 and 1918. A scheme is now in hand which ai at covering the country with a network of high-tens transmission lines with the view of supplying Du industries with cheap power; on its completion, t output of the country will be increased 76-fold. In t case of Italy, special State encouragement is being gi to the development of hydro-electric generation; the year November 1922-November 1923 no fewer th 134 concessions for water-power schemes were gran by the Government. A great scheme intended for t development of the resources of Calabria was begun 1923. In Czecho-Slovakia an Electricity Act w passed in 1919 providing for financial aid from t State for electrical development. Great activity the development of hydro-electric schemes has prevail in Canada in recent years. Although the populati of the Dominion is only about one-sixth that of t United Kingdom, Canada will by the end of 1924 getting from hydro-electric plant alone more pow than the engine capacity for the whole of the iron, ste engineering, shipbuilding, and textile trades in Gre Britain. As regards the supply of cheap elect power through hydro-electric plants, Great Brita cannot compare favourably with some other countri It is, however, becoming more evident every year th water-power is not an indispensable adjunct to ma electro-chemical and electro-thermal enterprises, a that other sources of power sometimes possess decid advantages.

The reason for Britain's comparative failure in t field of electrical development is traceable, the Repo rightly points out, to the state of our legislation, t effect of which has been gravely to handicap the geni of our engineers; "the power companies establish under the Power Acts have never been given an adequa chance to develop. They have suffered from the fa that already there had been established in all industri centres and in all our great cities, local and municip power supply undertakings which were organised on purely local basis." This circumstance precluded fr competition between the power companies and t existing authorities. The measures taken to remed this unfortunate situation are mentioned. As a fir step, a Coal Conservation Committee was establishe in 1917; it made a Report of the utmost importanc (Cmd. 9084). The matter was afterwards considere by another Committee, under the chairmanship

A. Williamson, which made certain specific re-mendations.

he Government of the day then took action and sed the Electricity (Supply) Act, 1919 (9 and 10 V. c. 100), in which was incorporated many of recommendations alluded to, and under its pro-ions have been brought into existence the Electricity ommissioners; in this body has been vested the general ctrol over the generation and distribution of electricity the United Kingdom. The Government did not ure in the Act of 1919 all the powers in relation to tricity supply it was seeking; the Bill was strongly posed in the House of Lords. Later, the Government ght and obtained further powers under the Elec-ity (Supply) Act, 1922 (12 and 13 Geo. V. c. 46), ich, though it improved matters to some extent, did effect, and was not designed to effect, the original ention, namely, that of replacing many small stations a few great power stations, with resultant economies coal and in money.

Dealing with the place of electricity in modern life, essential requirement, it is pointed out, is cheap wer; so far, this result has not been secured in Great itain on any notable scale. As an illustration, the e of Lancashire is quoted; this county is, from the hnical point of view, the most favourable area in gland for the generation and distribution of electricity eaply, yet, at the date the Coal Conservation Com-ttee of 1917 made its Report, the cost per unit was Lancashire nearly three times that paid in the North-st Coast district of England. Examples of a similar parity in the cost of energy are to be found in other rts of the country, and are due to the same cause; hereas in Lancashire a number of corporations are pplying energy in circumscribed areas, in the North-st Coast district a super-power station is trans-itting energy in an area of suitable dimensions rough well-placed main transmission lines. The ed for the elimination of waste, the importance of curing an increase in the use of electrical power and e financial and other advantages likely to accrue to e community from the removal of the smoke evil, e saving of by-products and a revival of rural dustries, are all duly emphasised in the Report.

The Committee makes allusion to the very conserva-ve policy which has been pursued by British railway mpanies in the matter of the electrification of their stems, and expresses the hope that in view of the ct that the financial and technical advantages of ectric over other forms of traction are being clearly emonstrated in foreign countries, our railway directors ill reconsider their policy in this matter, and further, at in the event of a national scheme of electric supply eing undertaken, the railways will give it the advantage of their co-operation. "Railway electrification would do much," says the Report, "to assure the economic and technical success of electrical production on a national scale"; in this view many eminent engineers concur. The Committee also points out that there are many recent processes, *i.e.* (1) the fixation of atmospheric nitrogen, (2) electric smelting, (3) the recovery of dyes, which are only possible economically in a country well equipped not only with electrical plant, but with *modern* electrical plant.

The unemployment problem also receives attention in the Report. The Committee attributes the failure in Great Britain to utilise the great unemployed labour force which has been available for construction purposes since the War partly to the limitation of the powers of the Electricity Commissioners. "We believe that it would have paid the State," says the Report, "to have expended large sums in the development of our resources by the provision of State credits, or the loan of public money at low rates of interest, for by so doing the internal economy of the country would have been improved and non-productive expenditure reduced."

In view of the present situation, the Committee is impressed with the necessity that exists for steps to be taken immediately to remedy the backwardness of Great Britain in electrical development. It recognises that the Electricity Commissioners have since their creation rendered most valuable services, but feels that this body is seriously handicapped owing to the insufficiency of its powers, and to some extent by the vested interests of the local undertakings, which, in the nature of things, are not and cannot be "as efficient as a national system developed in accordance with the most recent practice and supplying electricity in bulk from super-power stations." For these reasons, the Committee recommends that the powers of the Electricity Commissioners should be enlarged; this body could thus be placed in a position effectively to remove the obstacles which now block the way to electrical development in Great Britain.

It is mainly in two directions that the development of our great power-producing organisations is now being hindered: (1) by the existence of a number of small and inefficient local supply bodies; and (2) by reason of the magnitude of the undertaking and the uncertainty of financial success under existing conditions. To overcome the first of these difficulties, the Committee would like to see the Electricity Commissioners endowed with compulsory powers of acquisition, co-ordination, and regulation. To overcome the second of these difficulties, the Commissioners should, it is suggested, be granted full powers to employ every practicable means for encouraging and helping

electrical undertakers, public and private, who are prepared to establish generating stations of suitable capacity and type. Finally, the Report lays particular stress on the need for the Commissioners being authorised to empower electricity undertakers "to acquire compulsorily and at reasonable prices all land, rights of way, rights relating to water, and all ancillary rights, which may be necessary for the adequate execution of a national scheme."

The additional powers which it is recommended should be conferred on the Electricity Commissioners are undoubtedly large; however, few persons, if any, who are familiar with the electricity requirements of Great Britain are likely to cavil at the proposals made by the Committee. The situation which has to be dealt with is a very complicated one, and the reforms indicated, which undoubtedly are all urgently required, can only be brought about expeditiously by vesting in the Commissioners exceptional powers.

An idea as to how complicated the present situation is may be gathered from a perusal of the recitals of the "Order made by the Electricity Commissioners under Sec. 7 of the Electricity (Supply) Act, 1919, constituting the London and Home Counties Electricity District and establishing and incorporating the London and Home Counties Joint Electricity Authority" (H.M.S.O.). This Order was made on July 17 last after an investigation of many days' duration, and has been submitted to the Minister of Transport for confirmation; the interests and rights of the London County Council, the City Corporation, and 14 Power companies are involved, and it has been necessary to promote two Bills in the present session of Parliament in connexion with the Order. Situations which are equally, if not more, complicated exist in those parts of the country which have yet to be dealt with by the Commissioners.

It may well be asked, Why is it that the United States of America lead in the matter of electrical development? The answer to this question is to be found in the presidential address which Mr. W. H. Patchell delivered on March 21, 1924, to the Institution of Mechanical Engineers: this exceptional development, he tells us, is the direct outcome of the skill and zeal of those who handle the sales department of the American electricity supply undertakings. It will be evident, then, that if results similar to those obtaining in the United States of America are to be achieved in Great Britain, not only must additional powers be given to the Electricity Commissioners, but those responsible for the conduct of our electrical undertakings must also take a broad view of the commercial side of the business and adopt active measures for pushing the sale of their commodities.

Nature and Man in Tropical Africa.

Big Game and Pygmies: Experiences of a Naturalist in Central African Forests in Quest of the Okapi. By Cuthbert Christy. Pp. xxxi+325+56 pl (London: Macmillan and Co., Ltd., 1924.) 21s.

DR. CHRISTY'S "Big Game and Pygmies," ba as it is upon almost twenty-five years' c tinuous experience of tropical Africa, is a most inter ing and valuable book. The "external aspects organic nature" are not merely being modified human interference in Africa; they are there b rapidly and almost completely transformed. value of the observations so faithfully recorded in volume will therefore steadily increase. When at the varied face of Africa shall have been reduced dead level of cultivated monotony; when all its no animals and plants shall have been replaced by peac beasts of the farm and dull vegetation of econo importance, this will be one of the books that enable our heirs to appreciate what sacrifices we m in the names of civilisation and commerce.

An admirable account of the great equatorial r forest is given by Dr. Christy. Stating that it m once have stretched as an unbroken belt comple across the continent, he describes its destruction at hands of men. A good deal of the forest was destro before the advent of the whites; and to-day too, barbarous methods of agriculture employed by natives are responsible for a great deal. Strip a strip is cleared, by felling and by fire, along the fo margins. Ignorant of the art of maintaining fertility, the natives soon exhaust the virgin richn of the forest soil and proceed to make further depre tions upon the forest. The abandoned clearings quickly overgrown by grass and bush; but upon t sun-baked and exhausted soil rain-forest never appears. The forest once destroyed thus goes for ev and with it must disappear many of its inhabita Not improbably much of that progressive desiccat of Africa, about which so much has been written fr the days of Livingstone onwards, is to be regarded a direct consequence of the destruction of the equato forest. That is a matter worthy of consideration, a it is possible that the conservation of the remnants this great forest will loom as largely in African poli in a few years' time as reparations, for example, h done in those of Europe recently.

While native activity slowly but surely results in replacement of one African type of life by anoth white enterprise appears to be leading to the extir tion of the African biota. Enormous tracts of coun are being cleared of the indigenous vegetation a replanted by exotic plants of economic importan

For example, Dr. Christy foretells the time when South American Ceara rubber will replace the "profitless" bush and marginal forest and supply the world with gutta-rubber serviceable for all ordinary purposes at a penny a pound. From the selfish point of view of the dweller in remote temperate countries, that, no doubt, is good news; but from the point of view of a naturalist it is a deplorable prospect. A proportion of the native vegetable and animal inhabitants of Africa will doubtless succeed in adjusting themselves to the new conditions, but for a very large number, and among them the most interesting of the purely African forms of life, it spells extinction. Like the rain-forest, they are doomed if the commercial exploitation of the continent continues to proceed upon the present lines. So far as the larger mammalia are concerned, the process is hastened considerably, of course, by the rifles of ivory hunters and sportsmen. Dr. Christy says:

"As an indication of the amount of ivory that has come, and comes, out of the Congo annually, I may mention that I have seen lying in a trader's store at Boga about fifty fine tusks. . . . The trader informed me that the collection was the result of a month's buying from the natives. He also said that he received an average of one ton of ivory per month, about seventy-five or eighty fair-sized tusks, from his Kifuku branch store on the Ituri River south of Irunu. His was only one of many scores, perhaps hundreds, of similar trading and collecting stores, at which ivory was the chief cause of their existence."

In view of what we have permitted in our own African possessions, we have no right to point an accusing finger at that Belgian enterprise to which Mr. Christy pays a high tribute. But no scientific man can contemplate the slaughter on such a scale of slow-breeding animals like elephants without realising that it must result in complete extermination. He thought too that, in spite of this butchery, and notwithstanding the great wealth derived from ivory, the material at present existing in our museums is wholly insufficient to enable the zoologist to determine how many species or sub-species of the African elephant would be recognised, or to obtain a detailed knowledge of its soft anatomy and skeleton, does not allay that feeling of resentment which must arise in every scientific breast.

It must not be thought that Dr. Christy shares the despondence of the reviewer. On the contrary, he right-heartedly treats of things seen and deeds done; despondence comes only with reflection and at a distance. In this book, Dr. Christy, while primarily concerned with the Ituri forest and its inhabitants, gives us the fruit of experience gained while engaged in general scientific and medical research or upon hunting expeditions in many parts of tropical Africa. To him is due the credit of making one of the finest zoological collections ever brought together from any part of Africa. This collection was made for the Belgian Government, and is now housed in the museum at Tervueren. It is especially rich in mammals. Of these, the smaller species were worked out in the British Museum by Mr. Oldfield Thomas, and as a result our national collection has been greatly enriched by the joint labours of the collector in the field and the systematist at home.

The chapters upon the okapi, the African elephant, and the African buffalo are of especial interest. Dr. Christy's views upon the status of the various forms of buffalo, illustrated as they are by numerous photographs and some most excellent maps, will merit and receive the serious consideration of all mammalogists busied with the African fauna. Many interesting observations upon other mammals, such as the forest hog, chimpanzi, bongo, duikers, aardvarks, ant-eaters, small mammals, and upon other vertebrates and insects, are also recorded. Chapters dealing with the skinning and preservation of specimens and with matters relating to forest-hunting and armament will be found useful by those who contemplate collecting trips in Africa.

Lastly, but by no means least, Dr. Christy's accounts of the Ituri pygmies and other native races will make a strong appeal to all interested in anthropology and ethnography. M. A. C. H.

The Study of Textile Fibres.

The Textile Fibers: their Physical, Microscopical, and Chemical Properties. By Dr. J. Merritt Matthews. Fourth edition, rewritten and enlarged. Pp. xviii + 1053. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1924.) 50*s.* net.

TEN years having elapsed since the appearance of the third edition of this well-known text-book on the properties of textile fibres, the author has, for the purposes of the present edition, been under the necessity of re-writing, re-arranging, and greatly enlarging the volume, which now runs to upwards of a thousand pages, with more than four hundred illustrations.

In order to estimate the degree of success which has attended the very considerable labours of the author, due regard must be paid to his assertion, in the preface to the present edition, that "the great majority of his readers are neither chemists nor scientists"; for it is to this majority that the appeal of the book is directed. These readers, presumably those engaged on the practical side of the textile industry, are given an admirable summary of information upon the properties and uses

of all the important textile hairs and fibres, which is marked by a praiseworthy attempt to incorporate the results of recent advances in textile research made both in Great Britain and on the Continent.

The magnitude of such an attempt will be fully appreciated by any one actively engaged in textile research, and, in the result, defects of arrangement and lack of balance in the treatment of the various portions of such an enormous subject as the textile fibres are only to be expected. For example, wool and silk are both treated in an adequate and well-balanced fashion which might well have served as a model for the treatment of the other important hairs and fibres. On the other hand, in spite of the importance of the linen industry and of the amount of recent work carried out, both in Great Britain and on the Continent, upon problems connected with the structure, retting, and mercerisation of flax fibres, linen is dismissed with a short chapter of twenty-two pages, while the relatively unimportant minor seed hairs have sixteen pages devoted to them.

Of the seven chapters assigned to the cotton hair, some are unnecessarily elaborate, while from others important omissions are numerous. Those on mercerised cotton and the chemical treatment of fabrics for water- and flame-proofing are almost complete enough to form part of a technical handbook on these processes. Moreover, in the former, descriptions are included of the processes of schreinering and emerising which have no connexion with the problem of mercerisation.

Turning to the omissions, no account of the microscopic structure of the cotton hair can be regarded as complete which does not adequately take into consideration the work of Balls and Denham. Yet the former receives scant attention, while the latter is almost ignored. Again, in the chapter on the chemical properties of cotton there is no mention of the results of recent important researches on the nitrogen content of the cotton hair, the determination of copper number and the absorption of methylene blue by cotton. From the summaries of the physical and physico-chemical properties of cotton, notable omissions are the results of recent work upon the lustre and regularity of yarns and the swelling of single cotton hairs in solutions of sodium hydroxide, all of which are problems of vital concern to the cotton industry and of fundamental importance in textile research.

The reasons for such omissions will be sympathetically appreciated by the research worker on textile problems. During the last five years, the whole appearance of the field of textile research has been altered, chiefly owing to the activities of the research associations of Great Britain, and one is driven to the conclusion that an adequate summary of the origin, properties, and employment in industry of cott linen, silk, wool, and artificial silk is now quite beyo the powers of a single author. Such a summary m not only be a record of progress in several wide fiel all of which are being actively explored in every dir tion, but must also, at the same time, remove from position where it affects the views of those who a "neither chemists nor scientists," a large amount pseudo-science which has established itself in t technical literature. For example, the problem mildew in cotton goods is one of very great econom importance in the cotton industry. Yet, in Chapter xv (pp. 554-555) of the volume under review, the fi portion of a section on the action of mildew in cott is not only quite inaccurate and unscientific, but is al substantially the same as has been transferred fr one technical handbook to another since the appearan in 1879 of "The Sizing of Cotton Goods" by W Thomson. The section is completed by the additi of recent work by Thaysen and Bunker (unackno ledged) on the application of the viscose swelling t to damaged cotton, and of Denham on the destru tion of cotton hairs by micro-organisms. To t uninstructed all this work is of equivalent value.

The information on commercial varieties of cott in Chapter xii. might have been more carefully check No account is given of contemporary progress a tendencies in the cultivation of cotton within t British Empire and in Egypt; nor is it now qu correct to state that "India is destroyed as a possil source of supply [of long staple cottons] for the Engli mills." Such cottons are now being successfully rais in the Punjab and are rapidly bought up when ava able. Egyptian cotton is also dealt with in an inad quate manner. Hindi cotton is actually given as o of the principal varieties grown in Egypt, whereas has long been known as a pestilential weed-cott causing endless trouble in the cotton field, owing to t ease with which it crosses with cultivated varieties.

The chapters dealing with the properties and analy of jute, ramie, hemp, and the minor vegetable fib are particularly well done, and, with their illustratio represent a great advance on previous works. Th upon the analysis of textile fibres, fabrics, and yar and the testing of textile fabrics are similarly wort of praise; although a more systematic arrangement the tests would have been possible and some discussi of their comparative values useful.

In a work of such importance, errors and mispri should be lacking. During perusal a number have be noticed, *e.g.* the length of individual cotton hairs p. 339 is given as ranging from $1\frac{1}{2}$ to $1\frac{3}{4}$ inches; Nub cotton is spelt Unbari (p. 389); Smyrna cotton included as African (pp. 391 and 414); the diameter

sland cotton is given as 9·65μ (p. 414), whereas it d be at least 50 per cent. greater; the cross- ns of cotton hairs given in Fig. 201 are mostly e any ever seen by the reviewer, while the sections n in Fig. 186, p. 414, are those of hairs which have been partially mercerised. A misprint on p. 787 the diameter of ramie fibre as ranging from mm. to 0·06 mm. Such minor defects might be nated from subsequent editions.

Some Applications of Psychology.

Applied Psychology. By Prof. Bernard C. Ewer. . xii + 480. 10*s*. 6*d*. net.

How to Experiment in Education. By Prof. William McCall. (Experimental Education Series.) Pp. + 281. 12*s*. net.

Intelligence Measurement: a Psychological and tistical Study based upon the Block-design Tests. Prof. S. C. Kohs. Pp. xii + 312. 14*s*. net.

The Psychology of Algebra. By Edward L. Thorn- ke, Margaret V. Cobb, Jacob S. Orleans, Percival Symonds, Elva Wald, and Ella Woodyard. Pp. + 483. 12*s*. net.

(New York: The Macmillan Co.; London: acmillan and Co., Ltd., 1923.)

EVERY man considers himself an expert on psychological matters and is ready and willing ve his opinions. "Psychological" is a word used misused countless times to connote the human or ular side of any activity, until its scientific implica- is often buried under a sea of colloquial general- ons. No other scientific worker suffers, to the same ee as does the psychologist, from the unsought-for ularity of his subject. The chemist does not see emical Drama" staring at him from the posters he daily papers, nor does the geologist find a plex geological hypothesis used as a subject of ving-room conversation. Such general interest has en aroused in psychology that quacks and charlatans n it to their financial advantage. Prof. Ewer is ently smarting under these popular misrepresenta- ns of the subject. Again and again in his "Applied chology" he harps on the need for caution in accept- psychological beliefs. "As in the case of many nther development in the history of culture," he es, "this one has been characterised by great husiasm, overweening confidence, and a somewhat ritical evaluation of results. Gradually, however, see the ebullient assurance giving way to a more atious spirit of inquiry, the glittering but unsubstan- froth of superficial investigation disappearing, and olid precipitate of valuable information settling."

(1) Prof. Ewer has set himself the difficult task of writing a book which shall pass between the Scylla of technicalities intelligible only to the expert and the Charybdis of popular over-simplification, and he has succeeded singularly well. The book is divided into four parts covering the main field of applied psychology: "Aims, Principles, and Methods," "Education and Everyday Life," "Mind and Health," and "Industry and Commerce." In the first more general portion, the author gives an introduction to the chief mental factors and the methods of their interpretation and control. The rest of the book is devoted to a description of their practical applications. This is fascinating reading and is of immediate use as well as of interest, for every one will find some advice applicable to himself. Prof. Ewer has not originated any great new schemes for training or curing the mind, but he gives a clear and impartial account of the main theories on these matters. He is fully alive to the dangers of the various applications of psychology and shows how to avoid their abuses as well as how to promote their beneficial effects.

Especially interesting are the chapters on "Intellectual Efficiency" and "Everyday Psycho-therapy." Here, as in all his work, Prof. Ewer keeps as close as possible to common experience. As he says: "Psychology often succeeds only in giving precise form to what wise persons have long known, or reasons for what they have always done; but it is none the less desirable to have such exactitude and rationality scientifically established." If every one was to read this book before airing his views on applied psychology, there would be much less inconsequent babbling.

(2) "How to Experiment in Education" is a book that will save young educational psychologists from many a weary hour and tedious mistake. Prof. McCall has succeeded in summarising his experience in such a manner as to hand it on to those starting in his field. It is almost as if one is buying experience with the 12*s*. that is the cost of the book. The author remembers his own difficulties when his professors trusted to his "genius to supply the missing half of research methodology." "There are excellent books," he writes, "dealing with the statistical manipulation of experimental data, but there is little help to be found on the methods of securing adequate and proper data to which to apply statistical procedure. Training is given and books exist only for the last step of a several step process. As a result, the final step often becomes little more than statistical doctoring for the ills in the data." Prof. McCall starts, therefore, at the very beginning and gives advice as to the selection and formulation of the experimental problem and the procedure of making a bibliography. His fundamental criteria for constructing a test are particularly helpful.

Psychological research has the peculiarity, compared to other scientific research, that its subjects are human and bear human relationships to the investigator and each other. Prof. McCall gives good advice as to the errors that arise from the faulty selection of the subjects, from the bias of the experimenter, and from other important causes. About half the book is devoted to comparing the three fundamental experimental methods : the one group method, the equivalent group method, and the rotation method. The author discusses their various uses and gives a chapter to the computations for each method. A useful chapter is also given to "Casual Investigations," in which standardised methods of observation are suggested when experimentation is for some reason impracticable. The book concludes by discussing twenty-eight typical experimental problems, showing the best method to apply to each. The author has attempted to make his book particularly clear and concise by expressing all relationships by formulæ, but here perhaps he rather defeats his own ends, as the abbreviations used necessitate a three-page key.

(3) The position of intelligence tests is now thoroughly established, and it is acknowledged that they form a means of obtaining a quick and trustworthy measurement of an individual's general ability. Until recently, most intelligence tests have had a linguistic bias, but it is now realised that some people can do themselves justice more adequately when dealing with things rather than with words. Several practical or "performance" tests have been standardised with varying degrees of success, and some were used in the giant investigation of testing the whole American Army. There is, however, a great need for additional trustworthy tests of this type. Dr. Kohs has limited his book "Intelligence Measurement" to a description of a series of block-design tests devised by him, which he has proved to give results corresponding closely to other criteria of intelligence. The tests consist of a series of coloured blocks which must be put together to make patterns of such varying degrees of difficulty that some can be passed by a five-year-old child and others are difficult for an adult. The technique of standardising the tests is extremely well described, and the ninety tables of figures in the explanation should serve as a warning to those who believe that to devise an intelligence test it is only necessary to think of some questions and give them to a few children.

(4) Any teacher of algebra, whether he started this term or has had forty years of experience, will be stimulated by reading Prof. Thorndike's "Psychology of Algebra." Experimental proof is worth a lot of theorising, and this book is the outcome of large scale investigations on many aspects of the subject. Many of the topics are quite original, but the more fam problems, such as the best order of presenting ma and the optimum distribution of practice, are neglected. An interesting study is made of the us algebraical knowledge to science students. *Quest naires* were sent to lecturers of the various physical social sciences, and text-books were analysed to see relative practical value of the different algebraic to But although such applications of the subject studied, its intrinsic value is also realised—the ap of "the love of thought for thought's sake by those can play the game of thought well."

WINIFRED SPIELMA

The Cactus Family.

The Cactaceæ : Descriptions and Illustrations of Pl of the Cactus Family. By N. L. Britton J. N. Rose. Vol. 4. (Publication No. 248.) vii + 318 + 37 plates. (Washington : Carnegie I tution, 1923.) 6.50 dollars.

THE issue of the fourth volume of "The Cactac brings this sumptuous monograph of the fa to a conclusion. Previous volumes have been cussed in NATURE, vol. 107, p. 580, and vol. 111, p.

Vol. iv. is carried out in the same excellent ma as the preceding volumes, and completes the acc of the smaller and more popular species of this fan It deals with the remaining three subtribes, nam the Coryphanthanæ, consisting of 14 genera, of w the principal is the familiar genus Mammillaria (he renamed Neomammillaria); the Epiphyllanæ, sisting of 9 genera, which of all Cacti are probably greatest favourites with horticulturists ; and Rhipsalidanæ, consisting of 8 genera. There is als appendix and an index to the whole work. The vol is beautifully illustrated with 37 fine plates, mos them coloured, and 263 figures in the text. references are also given throughout the work figures that have appeared in other books.

Altogether (including two new genera and 24 species described in the appendix) this volume tr of 33 genera and 358 species, the largest genera b Neomammillaria, 150 species ; Rhipsalis, 57 spec Coryphantha, 37 species ; Epiphyllum, 16 species ; Thelocactus, 12 species ; 14 genera are monotypic, the others have only 2-8 species each. In the er work, 124 genera and 1241 species are described illustrated by 137 plates and 1119 figures ; of thes considerable number are described and figured as

About two-thirds of the species dealt with in present volume belong to plants known in gar under the generic names of Echinocactus and M millaria ; the latter name, however, has now

d by the authors to Neomammillaria, because the
Mammillaria properly belongs to a genus of
It is unfortunate that previous monographers
ti had not long ago recognised this and changed
me in accordance with the rule of priority, for the
Mammillaria has become so firmly established
oks and gardens for these Cactaceæ that it will
ficult to supplant it by the new name.

other generic change of name, now rightly made,
ought to have been done long ago by previous
graphers, is to retain the name Epiphyllum,
was first published in 1812, for those plants
n in books and gardens under the name of Phyllo-
s, which was not published until 1831. The
s known in books and gardens under the name of
hyllum belong to the genera Zygocactus and
mbergera.

the genera, 12 are published in this volume for
irst time, and there are 3 others that have been
shed elsewhere since the issue of the first volume.
ough some of the genera in this work will probably
e upheld by future workers, the authors have con-
ntly followed their plan of utilising all vegetative
structural characters that differ in degree or nature
he formation of genera, with the result that the
es having the same characters in common are
ciated together in a more complete manner than
erto.

he authors deserve the hearty thanks of all lovers of
i for the admirable and efficient manner in which
have completed their task. In doing this they
e fortunately been better equipped for it than any
ious monographers of the group. For not only
e the authors themselves visited some of the regions
re these plants grow, and studied them under
ural conditions, but they have also received great
from many others interested in the group who reside
r have visited the various countries in which Cacti
w wild, and have contributed quantities of living
erial, photographs, and information appertaining
hem, all of which has been utilised in constructing
fine monograph; the result being that, not only
the first monograph of Cactaceæ that has been
lished in the English language, but is also one that
ir in advance of the German works upon the subject
t have hitherto held the field.

t cannot be expected that a work of this kind is
hout errors, but to the knowledge of the writer the
thors have done their best to avoid them. The
thing wanting appears to be a series of plates
rly illustrating the distinctions between the various
era. Perhaps the authors may see their way to
ply them as a supplement.

Our Bookshelf.

The Work of the Royal Engineers in the European War, 1914–1919. Work under the Director of Works (France). Part 1: Historical; Part 2: Technical; Part 3: Maps and Plates. (Published by the Secretary, Institution of Royal Engineers, Chatham.) Pp. viii+279+6 maps+81 plates. (Chatham: W. and J. Mackay and Co., Ltd., 1924.) 21*s.*

This volume from its very nature lacks some of the thrilling interest which characterised some of the earlier volumes of the series to which it belongs, owing to the fact that it deals with a struggle against difficulties carried out for the most part at a distance from the enemy. When enemy action upset the plans of the Director of Works it was, save in the case of the bombing of hospitals, power stations, or important bases, generally due to a change in the plans of the whole army, in which the Director of Works had become necessarily involved. The struggle outlined in this volume is one to meet the demands of constant expansion and development with inadequate resources of labour, personnel, and equipment. Granted the conditions, it is marvellous how much was achieved and, on the whole, how successfully new demands were met.

The volume under review contains six chapters outlining the changes in each year of the War, the developments characteristic of successive phases, followed by twenty-five chapters of a technical nature discussing the separate branches of work for which the Director of Works became responsible. It is well illustrated by maps of the lines of communication areas, and by numerous diagrams of camps, larger buildings, huts, machines, and plant of various types. Much useful information is given about such items as camp sanitation, disinfection, and protection against hostile aircraft. On the whole, the book is of the nature of a technical guide to the engineer officer who is concerned with the design of camps.

The human element is rather lacking in the book, though we may mention the consternation caused among the inhabitants of Rouen when it was discovered that the goats in the Halle des Blés, protected from inclement weather by shutting all doors and windows, needed ventilation, and when on the windows being opened the pent-in effluvium of the goats rushed out and spread about the neighbourhood. Another human touch is supplied by the provision that on the lines of communication all hospitals *must* be lit by electric light, ammunition, supply, and ordnance depots *should* be lit, and camps, remount depots, and veterinary hospitals *might* be lit, if a supply could be obtained locally at a reasonable cost.

Die Entfaltungsbewegungen der Pflanzen und deren teleologische Deutung. Ergänzungsband zur "Organographie der Pflanzen." Von Prof. Dr. K. Goebel. Zweite, neu bearbeitete Auflage. Pp. x+565. (Jena: Gustav Fischer, 1924.) 20 marks.

The work of Prof. Goebel, of the University of Munich, is known to all students interested in the morphology and physiology of plants. His "Organographie der Pflanzen" was translated into English

by Prof. (afterwards Sir) I. B. Balfour and published by the Clarendon Press, vol. i. in 1900, vol. ii. in 1905. Since these dates a new German edition has been appearing (1913–23), and to it there was added in 1920 a supplementary yet independent volume dealing with the movements of attached plant-organs. The first edition of this last volume was quickly exhausted, and a second, considerably enlarged, has now been issued.

Much of Prof. Goebel's work can be described as a synthesis of morphology and physiology, and the present work is no exception. Here, however, the author has set himself a definite problem, namely, to investigate the kinds and methods of movements shown by plant-organs, and especially to decide whether or not they are adaptational. The word "Entfaltungsbewegungen" would seem scarcely to cover all the contents of the book, for the stimulated movements of floral parts and of sensitive plants, and also "sleep-movements," are considered, in addition to movements connected with the unfolding, growth, and development of buds, leaves, and flowers. The various movements are fully described in the text, which is illustrated by 278 figures, more than half of which are reproductions from photographs.

The number and variety of species on which observations are recorded, and on many of which experiments were made, enable Prof. Goebel to put forward his views with some confidence, albeit he is not dogmatic. Throughout the work he is decidedly sceptical concerning the various teleological theories which have been proposed, largely under the influence of Darwinism, as explanations of the movements of plant-organs. Unavoidable reaction, not purposeful response, is suggested again and again. That the movements often are relatively advantageous is not to be denied, and it may be granted that Natural Selection would tend to eliminate any species which had developed decidedly disadvantageous movements, but the advantages or disadvantages are secondary, not the purpose of the movements the origin of which has been fortuitous. Goebel further emphasises the manifold ways in which the movements of plant-organs occur, and it seems possible that the usual classification is misleading and has itself suggested false teleological conclusions. At least, the extensive studies which have been published by Prof. Goebel indicate that generalisations based on limited, even if intensive, observations and experiments may often prove false. W. B. T.

Medical and Veterinary Entomology: a Textbook for Use in Schools and Colleges as well as a Handbook for the Use of Physicians, Veterinarians and Public Health Officials. By Prof. William B. Herms. Second edition, completely revised. Pp. xv+462. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1923.) 28*s.* net.

In the second edition of this work the chief new features are the historical introduction, dealing with the development of medical entomology, and the additions to various chapters of material derived from the author's experience as a sanitary officer in the U.S. Army during the War. The external features used in classification and the life-history of the insects of medical and veterinary importance are considered, but internal anatomy is dealt with only in a few ca Methods of control are carefully discussed, references given in the most important cases to original sources of the respective methods. The n detailed chapters are those devoted to lice, mosquit house-flies, larvæ which produce myiasis, and ti and these are the chapters which will be most usefu the majority of readers. The accounts of other inse *e.g.* fleas, are less satisfactory from the medical p of view; thus, although the characters of *Xenops cheopis* are given there is no reference to *X. astia* o *X. brasiliensis*—which the reader should be sh how to differentiate from *X. cheopis*, and the aut is in error in regard to the structure labelled as hy pharynx in the figures of the fleas shown on p. In the brief account of the life-history of *Dipylid caninum* the work of Joyeux (1916) might have b referred to. The observations of Dr. and Mrs. Cor (1922) on the life-cycle of *Filaria* (*Loa*) *loa*, and work of Christophers (1922) on the segments of mosq larvæ, were perhaps published just too late to rec notice. In the description of Fig. 20 the term p (of the house-fly) should be replaced by pupari Good drawings would have been more helpful to reader than certain of the photographic illustrati provided, *e.g.* Figs. 91, 140, 141, 143, 152, 161, 180, 210.

The book has no doubt been written with partic reference to the needs of medical and veterin students and public health officials in the United Sta but the greater part of the work has a general appl tion to the conditions in warm climates elsewhere, will be found useful by those who desire a con account of the biology and methods of control of insects which attack man and animals.

A Third Year Experimental Chemistry. By W. Crabb. Pp. viii+247. (London: Mills and B Ltd., n.d.) 3*s.* 6*d.* net.

On leaving the university and entering a second school to teach science, the young graduate quic finds that he has much to learn, and as he progre he realises more and more the folly of spoon-feed his pupils on "academic" science. If he is keen progressive, he will construct his own notes and p together the scaffolding of a potential text-book; in compiling such data he will gather valuable perience. Whether his work will be published not depends upon many factors: ambition, the s regarding instinct, inertia, modesty—and publishers

The small work under review appears, rightly wrongly, to have originated in some such manner the above, and it will be very useful not only to author, but also to other teachers, if they do not pr their own notes. The author is evidently a clear conscientious teacher, and the only adverse criticism be offered is that he covers too much ground; w the exception of pupils who are specialising betw 17 and 19 years of age, it is very doubtful if any ordin school class could adequately assimilate more than the contents of this book in a working school year, s of 30 weeks; and probably only a small minority pupils could tackle the work successfully after a t years' course in elementary chemistry. To take

on as an example. The sixth lesson, on diffusion liquefaction of gases, comprises revision of experi-nts on these subjects, Graham's law, and practical olications; then some historical notes leading to a y sketchy notice, without diagrams, of liquefaction gases by self-cooling; and lastly, as "topics for cussion," commercial liquefaction of gases, separa-n of oxygen and nitrogen from liquid air, uses of uid air, methods of nitrogen-fixation, uses of liquid phur dioxide, chlorine and ammonia, carbon-dioxide now."

t is regrettable that attempts are still made in our ools to turn out ready-made chemists and physicists. lightened university teachers, and employers, do not nt students of this kind; they want youths with ute and alert minds, having a sound knowledge of mentary principles and a keen desire for more.

abische Alchemisten. 1: Chālid ibn Jazīd ibn Mu'āwija. Von Julius Ruska. (Heidelberger Akten der von-Portheim-Stiftung, Heft 6.) Pp. 56. (Heidelberg: Carl Winter's Universitätsbuchhandlung, 1924.) 3 marks.

his scholarly dissertation upon Khalid ibn Yazid will ceive a hearty welcome from all those who are terested in the history of chemistry. It must serve a foundation for all future work upon Khalid, who is e of the most attractive of early Muslim chemists. uch that is legendary has been associated with him om a very remote period, and this apocryphal matter ls naturally increased with the passage of time. rof. Ruska carefully examines the principal sources ir the life of Khalid and is able to show that they ntain numerous inconsistencies and anachronisms. is clear that none of them is entirely trustworthy, ad the same may be said of the various books and oems in Arabic ascribed to Khalid, which are probably ll spurious, even though they may contain authentic assages.

Prof. Ruska considers the Khalid-Morienus story at me length, and rejects it. He explains that in its arliest form the story makes Stephanus, contem-brary with Herakleios (died 641), the teacher of halid (died 704), but suggests that when Muslim istorical knowledge came to recognise that Stephanus ad died before Khalid was born, a "pupil of tephanus," Marianus or Morienus, was invented to ct as a link between the two.

All the Latin works which pass under the name of halid or Morienus are declared by Ruska to be alsifications, particularly the "Liber Secretorum Artis ompositus per Chalid filium Jaichi," and "Liber rium Verborum Kalid Regis acutissimi." While this s probable enough, there is good reason to suppose hat certain sections are of extremely ancient origin, as hey may be found in Arabic in the "Kitāb al-Muktasab" (*c.* 1300), which goes back to "Ares" and Khalid for its authorities and is quite independent of he line of development passing through Rhazes and he Spanish Arabs.

One small error may be noted. On p. 49, Prof. Ruska attributes the "Rutbatu'l-Ḥakīm" to Maslama al-Majriti; it was in fact written about 100 years after Maslama's death. E. J. H.

The Fauna of British India, including Ceylon and Burma. Edited by Sir Arthur Shipley. *Birds.* Vol. 2. By E. C. Stuart Baker. Second edition. (Published under the authority of the Secretary of State for India in Council.) Pp. xxiii + 561 + 8 plates. (London: Taylor and Francis, 1924.) 30*s.*

THE second of the volumes on Indian birds undertaken by Mr. E. C. Stuart Baker, for the "Fauna of British India" series, is a worthy successor to the first. It contains a further instalment of the Passeres from the Cinclidæ (Dippers) to the Regulidæ (Goldcrests, etc.), and deals with 473 forms in a remarkably thorough manner. So far as is known, the vernacular names, nidification, and habits of each form, in addition to a complete systematic description, are given, and it is hoped that further observations under the first three headings will be recorded by Indian ornithologists. A noteworthy feature, as in the first volume, is the numerous coloured plates executed by the author himself, which are a credit to his artistic ability. A few eggs and nests might with advantage have been figured; a series of the former as a coloured plate would have made a fitting frontispiece, or a figure of the egg of each of the forms of which plates have been given might have been included in them. The absence of a full synonymy is again noticeable, but we learn with satisfaction that a sixth volume has been sanctioned which will contain a full synonymy of the forms dealt with in the previous volumes, and such addenda and corrigenda as are necessary.

The "Fauna of British India" series is, we believe, meant primarily to serve as complete handbooks on various groups for Indian collectors, and if this object is to be fulfilled in dealing with the birds, Mr. Baker would do well to take the opportunity of introducing a brief but complete introduction to Indian ornithology, containing notes on collecting, geographical distribution, and a map, with some account of the topography of the region insomuch as it concerns the Indian birds, in the sixth volume of his series. Mr. Baker's extensive knowledge of Indian field ornithology would make such an introduction most valuable. He is to be congratulated on producing a series which again makes it possible for those who have not his special knowledge to identify Indian birds correctly without wading through a mass of confusing synonymy.

C. DOVER.

Engineering Non-Ferrous Metals and Alloys. By Leslie Aitchison and William R. Barclay. (Oxford Technical Publications.) Pp. xx + 300. (London: Henry Frowde and Hodder and Stoughton, 1923.) 21*s.* net.

A TRUSTWORTHY account of the non-ferrous metals and alloys used for engineering purposes has been needed for some time, and Dr. Aitchison and Mr. Barclay have made an excellent effort to meet this need. Without entering into processes of manufacture, they discuss generally the properties of cast and wrought metals, and then describe in detail the several metals and alloys with their physical and mechanical properties, together with their principal uses. The statements of the authors are based on a wide practical experience, and may be regarded as authoritative. The section on the alloys of nickel will be found

particularly valuable. The metallographic side of the subject is less fully dealt with, and the photo-micrographs included do not constitute a representative series. The equilibrium diagrams might well have been omitted, as they bear no indication of the phases present, and the copper-aluminium diagram on p. 125 is impossible. The engineering reader would not derive any information from such diagrams, and the metallurgist would have to look elsewhere for an explanation of them. Mechanical testing is well and clearly described, but it is rather surprising that the now familiar Erichsen test is not included, it being greatly superior to the crude cupping test.

The book was completed too early to admit of the incorporation of the detailed report of the Alloys Research Committee on light aluminium alloys, but we may expect that this section will be expanded in a future edition. The same may be said of the die-casting alloys, as to which more information is now available than the authors have provided. It is certain that the book will be welcomed by engineers, and will be found useful by metallurgists.

The Literature of the Charadriiformes from 1894–1924: with a Classification of the Order, and Lists of the Genera, Species, and Sub-species. By Dr. George C. Low. Pp. xi+220. (London: H. F. and G. Witherby, 1924.) 12*s.* 6*d.* net.

Much labour has obviously been expended in the preparation of this work of reference, and ornithologists must be correspondingly grateful to Dr. Low for his having placed so useful a tool in their hands. Its purpose is to supply a complete guide to the literature dealing with the Charadriiformes in the thirty years which have elapsed since the publication of volume xxiv. of "The British Museum Catalogue of Birds." The labours of other workers in this field will be greatly facilitated by the availability of these collected and classified references. A preliminary chapter discusses the classification and nomenclature of the group, and a second gives references to works of a general kind bearing on the subject. The rest of the book is devoted to references grouped under the names of the ninety-seven genera, in ten families, which Dr. Low admits to the order, and under each genus they are arranged chronologically. Some idea of the bulk of modern ornithological literature may be gathered from the fact that the references to this one order, admittedly an important and interesting group, fill about two hundred pages. Frequent use in actual work is the only true means of testing a book of this kind, but such checks as one can readily impose show that Dr. Low has performed his laborious task with the thoroughness and accuracy for which it called.

The Irish Setter: its History and Training. By Colonel J. K. Millner. Pp. 80+8 plates. (London: H. F. and G. Witherby, 1924.) 5*s.* net.

From the introduction we learn that this is the first book devoted solely to the Irish setter. It cannot, however, be regarded as more than a random collection of miscellaneous notes about the breed, and some of its most distinguished representatives, with an admirable chapter on training and a clear description of the points of the breed as approved by the Irish Red Setter Club. The origin of the Irish setter is apparentl shrouded in oblivion. Beyond the suggestion that i has been derived from the red spaniel of the eighteent century, used largely in hawking, and that its develop ment dates from the beginning of the practice o shooting at flying birds in the last half of the sam century, there is nothing really definite that is known and no records are available which help to establish it history. A century ago there were apparently tw distinct strains—red, and red and white, the latte predominating; but with the introduction of dog show and the somewhat arbitrary requirements of fanciers the red-and-white strain has largely disappeared. Fo show purposes only the merest traces of white on th head, chest, throat, and toes are allowable. Mr. S. W Carlton contributes the introduction, and the book i illustrated by eight half-tone blocks of celebrated Iris setters, taken from the dogs themselves or from o paintings.

Automatic Telephones. By F. A. Ellson. (Pitman' Technical Primers: Double volume.) Pp. xii+215 (London: Sir Isaac Pitman and Sons, Ltd., 1924. 5*s.* net.

At first sight, automatic telephony appears to be hopelessly complicated subject. Yet next year it wil be necessary for all telephone subscribers to begin t get a working knowledge of it, as the British Post Offic decided a year ago that automatic equipment is to b adopted in all important areas. We wonder whethe in the future it will be well known that the "doubl dog" is knocked away until the wipers clear the bank and that during this process the stationary dog support the weight of the shaft. In any case these terms wil have to be included in technical dictionaries. The lis of British standard terms made by the Engineering Standards Association and included in this volume i excellent. The advantages of the automatic syste are the large savings that can be effected in the annua charges, the continuous day and night service, and th increased efficiency and accuracy. The disadvantage are the greater capital cost and maintenance charges and the increased liability to faults at the subscribers end. To the intelligent reader who wishes to under stand the basic principles of the ordinary systems i use, we can recommend this book.

Anatolica. By Harry Charles Luke. Pp. xii+210+ 40 plates. (London: Macmillan and Co., Ltd. 1924.) 16*s.* net.

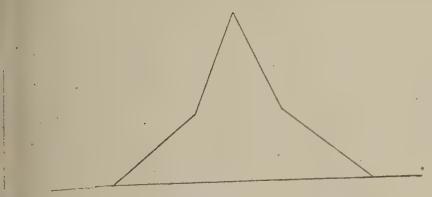
In this volume Mr. Luke again shows the knowledg and insight, together with the charm of style, that have made notable his previous volumes on the Near East. Among the flood of books on various parts of the eastern Mediterranean, it is rare to find one written with more authority or marked by greater conciseness and first-hand observation. It is entirely unpolitical, and consists of a series of short essays on various towns and districts, including Mount Athos, Salonika, Adrianople, Cyprus, the Holy Sepulchre, Petra, and the cities of Transcaucasia. The chapters on Cyprus are among the most vivid in the book, and recall the charm of the island. There is a quaint and sufficient map, and the illustrations are well chosen. The coloured frontispiece of Mount Ararat is excellent.

Letters to the Editor.

Editor does not hold himself responsible for nions expressed by his correspondents. Neither he undertake to return, nor to correspond with writers of, rejected manuscripts intended for or any other part of NATURE. *No notice is en of anonymous communications.*]

pecific and Latent Heats of Iron and Steel.

a letter on this subject published in NATURE of 19 (vol. 113, p. 566) it was shown that if the *rature* of the metal is raised continuously, the ting expansion plotted in terms of time appears smooth curve exhibiting no peculiar features.[1] on the other hand, *heat* is supplied in the same the variation of temperature, and therefore of nsion, is dependent on the specific heat of the

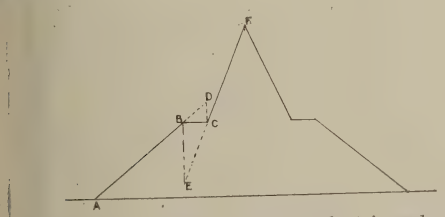


—Diagrammatic representation of the extension of a material when at is supplied and withdrawn at a constant rate; and the specific at changes at a definite temperature.

rial so that the rate of extension is (*cæteris ous*) inversely as the specific heat.

I the rate at which heat is supplied is uniform, if the only change in the metal at the critical perature is in the specific heat, the curve repre- ng the extension during a cycle of heating and ng would be four straight lines as in Fig. 1.

I however, in the change from the low to the high perature state, heat is rendered latent,[2] and pro- d that the change can be brought about by an finitesimal excess of temperature above the critical le, the extension diagram will be of the form n in Fig. 2.



2.—Conditions as in Fig. 1, except that heat is rendered latent at e temperature of the change of specific heat. The quantity of heat hich becomes latent is equal to that which would raise the temperature fficiently to cause the extensions CD or BE, according as the specific eat is taken as that belonging to the branch AB or CF.

he latent heat is that which would cause an ex- sion CD or BE, according as the specific heat is ln as having the low or high temperature value. Vhen, as in my experiments, the variation of tem- e ture in heating depends on the excess of heat plied over that lost by radiation and convection, n in cooling on the difference of temperature eveen the heated wire and its surroundings, the traight lines in Figs. 1 and 2 become exponential curves, and the typical heating and cooling diagram is similar to that in Fig. 3.

The curved form of the junction between low and high temperature branches shows that the material is in an unstable condition at the critical temperature, and that to start the transition from one state to the other, the critical temperature must be exceeded in heating, or passed in the opposite direction in cooling, but that once started it proceeds in suitable conditions, with sufficient rapidity to reduce or raise the temperature of the wire, and thereby alter its length. To show these effects to advantage the diameter of the wire must be small enough to ensure that the difference of temperature between its surface and interior is small.

In the letter of April 19 previously alluded to, it was shown that the critical temperature was chiefly dependent on the proportion of carbon present in the metal, and it was suggested that in iron free from carbon the critical temperature might be found to be that corresponding to the intersection of the curves appropriate to the two specific heats. A reference was also made to the difficulty of obtaining iron containing no trace of carbon.

It seemed possible that such iron might be prepared by the "Thermit" process, and within the last few weeks I have experimented with wire drawn from an ingot of Thermit iron made at the Davy-Faraday Laboratory from pure materials. Lengths of this wire were heated with graphite for various periods in

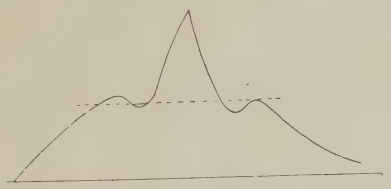


FIG. 3.—Diagram of the extension of the same material as that of Fig. 2, when the net increment of heat is proportional to the excess of heat supplied above that lost in the same time by radiation, etc., and the loss of heat during cooling is proportional to the excess of the temperature of the material above its surroundings.

a combustion furnace, and the results of these trials are shown in Fig. 4.

It should be stated that the analysts find that the Thermit ingot contained something like 0·04 per cent. of carbon, and also that in a sample of electrolytic iron which the National Physical Laboratory were kind enough to supply the carbon percentage was 0·065.

In both cases the origin of the carbon is unknown. An examination of the curve in Fig. 4 shows that even a thirty minutes' heating in graphite causes a slight drop in the critical temperature and some change in the character of that part of the curve which indicates the extension while change of state is in progress.

These changes become more marked as the time of heating in graphite is prolonged, and when this reaches five hours, it is seen that there are two separate pauses at different temperatures in the heating curve and a double reheating during cooling.

All these peculiarities can be explained by supposing that the outer parts of the wire have been converted into a mild steel while the core remains comparatively pure iron: so that each part changes its state at the temperature appropriate to its carbon content.

The diagram Fig. 4, *a*, for the Thermit iron which has not been in contact with the graphite, shows a critical temperature slightly higher than that for the "Armco" iron referred to in my letter of April 19, but in other respects the results are identical; and in

[1] he actual coefficient of expansion of iron at first increases with the erature, but diminishes as the melting-point is approached.

[2] t is not unlikely that something of the same kind happens with any ent which assumes an allotropic form on heating. If a small quantity f phur in the plastic state is "chawed," it soon resumes the crystal- n form, and becomes gritty in the mouth, with a very sensible rise of erature.

all the irons and steels I have used, the ratio of the low and high temperature specific heat is very nearly three to one.

In making steel by the cementation process on a commercial scale, I believe that iron bars exceeding 1 square inch in cross-section are heated in charcoal for a fortnight or more; and as the carbon probably passes into the metal by diffusion, it might be expected that in the case of an 0·02 in. diameter wire,

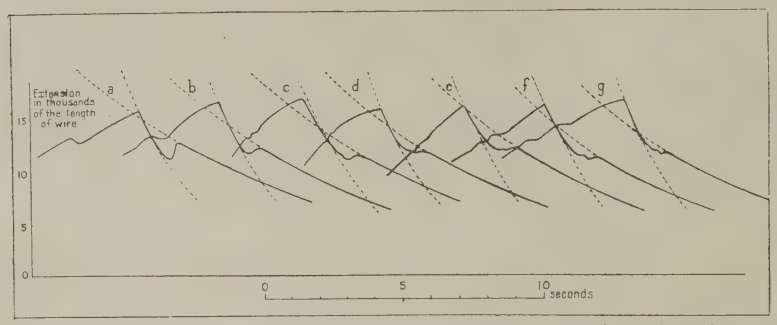

FIG. 4.—Tracings from diagrams of extensions during heating and cooling of wires drawn from "Thermit" iron, the wires being subsequently heated in graphite for the following time:

Diagram.	Minutes.	Diagram.	Minutes.
a	0	*d*	180
b	30	*e*	250
c	60	*f*	320

saturation would be reached in a much shorter time. It would seem, however, judging from the lower of the critical temperature in diagram *f* of Fig. 4, that the five hours' heating has only produced a coating of very mild steel. The temperature at which cementation is carried out probably has an important effect on the rate of diffusion, and further experiments on this subject will be made with purer samples of iron, if such can be obtained. A. MALLOCK.

August 8.

The Rotatory Dispersion of Tartaric Acid.

EIGHTY-EIGHT years ago, Biot (*Comptes rendus*, 1836, 2, 542) showed that an *anomalous* rotatory dispersion could be produced by superposing two *normal* partial rotations of opposite sign and of unequal dispersion. This general theory of the origin of anomalous rotatory dispersion can be developed in two ways, according as it is supposed that a partial rotation of opposite sign is produced as the result of a chemical change in the optically-active molecule, or that the presence of two opposite partial rotations is one of its inherent physical properties. In the Bakerian lecture of 1921 (Phil. Trans., 1922, A, 222, pp. 249-308) we adopted, for the case of tartaric acid, the former explanation.[1] This was in harmony with the conceptions of Biot himself, since he attributed the variations in the rotatory power of this acid, *e.g.* in aqueous solutions, to chemical and not to physical causes; this point of view had also been stated in a very precise form by Arndtsen in 1858 (Ann. Chem. Phys., 1858, 54, p. 421). The same explanation has since been adopted by Astbury (Proc. Roy. Soc., 1923, A, 718, p. 527; NATURE, July 26, p. 122) as a sequel to his X-ray examination of the crystals, and by Longchambon (*Comptes rendus*, 1924, 178, p. 951) as a result of his study of their optical rotatory power. There is therefore a strong consensus of opinion amongst all those who have recently worked on the subject, that the anomalous rotatory dispersion of tartaric acid is related very intimately to its ability to undergo a reversible chemical change.

[1] The latter explanation has been adopted in the case of α′-bromocamphor.

Whilst the existence of this chemical change admitted by all the workers named above, differen of opinion have arisen as to the exact nature of change. Arndtsen adopted a perfectly general v as to the nature of the dextro- and lævo-rotat components. In the same way, Longchambon (w identified the lævorotatory component with ordinary crystals of the acid, and named two components as α- and β-tartaric acid) offered opinion as to the nature of β-tarta acid. In the Bakerian lecture, h ever, after a careful study of all available evidence, we felt justif in concluding that the acid exists two *isomeric* forms of opposite rot ory power. Astbury, on the ot hand, postulated a reversible *p meric* change, depending on " tendency of the molecules to bu themselves up into a lattice . . . e in dilute solutions." This view been shown to be untenable in case of ethyl tartrate (Lowry a Cutter, Journ. Chem. Soc., 1924, pp. 1465-1470), where determi tions of molecular weight can made without the complicati which would arise from electrol dissociation in the case of the acid; and, although it is p fectly true that "the dextrorotatory system predominates in dilute solutions" of the free acid *water*, as required by Astbury's hypothesis, dil solutions in *acetone* are *lævorotatory* (Austin and P 1924, unpublished observations). The progressive composition of "crystal molecules" into "chemi molecules," which was first put forward by Land in 1879 as an explanation of the mutarotation of sugars, appears then to be equally invalid w brought forward again as an explanation of anomalous rotatory dispersion of tartaric acid.

Astbury suggests that the individual molecules tartaric acid contain an *intramolecular* spiral of f carbon atoms, which is *dextrorotatory*, whilst crystals contain also an *intermolecular* spiral (form by the juxtaposition of hydroxyl-groups in conti ous molecules) which is itself *lævorotatory*, but *always accompanied by the fully developed dextrorotat spiral*. Longchambon, on the other hand, suppo that whilst the *solutions* contain both a dextrorotat and a lævorotatory component, these are individ chemical compounds and may therefore be separa from one another; the *crystals* therefore contain o the lævorotatory component (α-tartaric acid), *dextrorotatory component (β-tartaric acid) having b eliminated completely during the process of crystalli tion.*[2] These conflicting views can be tested by amining the relevant rotatory dispersions. In case of aqueous solutions of tartaric acid, the rotat dispersion can be represented by the equation:

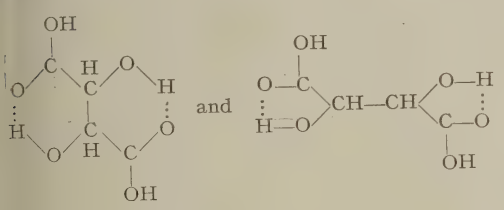
$$\alpha = k_1/(\lambda^2 - 0{\cdot}03) - k_2/(\lambda^2 - 0{\cdot}074).$$

The esters give similar equations but with rat smaller values for the second dispersion-consta If the lævorotatory crystals of tartaric acid gave o the negative partial rotation of the aqueous solutio (as Longchambon supposes), the dispersion-ra $\alpha_{4358}/\alpha_{5780}$ would be about 2·2, whereas *lar* values would be given if (as Astbury suggests) negative rotation were masking a smaller positi term. The ratio 2·14 actually observed by Lor chambon is almost identical with the value calculat from our equation, and therefore affords a conclusi

[2] Compare the complete separation of one of a pair of labile isomerides crystallisation from solutions of α-glucose or of nitrocamphor.

cation of his claim to have separated the lævo-ory component completely from the dextro-ory component which is formed from it in ion.

his original paper, Astbury ascribed the anoma-dispersion of tartaric acid to "strings of mole-, connected together at the hydrogen junctions" e hydroxyl-groups, which he represents as points ontact between contiguous molecules in the als, thus —OH HO.CO—. When it is realised the X-ray analysis of organic compounds deals with the orientation and spacing of *molecules*, gives no information as to the positions of the idual *atoms*, it may be doubted whether there is experimental foundation whatever for the wholly obable view that the molecules of tartaric acid held together *by the mutual attraction of two ms*. The idea that two hydroxyl-groups attract another is indeed an old one; but since Bragg blished the crystal-structure of ice, it has become nt that this action depends on a mutual attrac-between the hydrogen of one molecule and the gen of another, a view that has recently been de-ped under the title of "Bivalent Hydrogen" by . Lewis in America, and in Great Britain under itle of "The Co-ordination of Hydrogen" by one ne undersigned. Considerations of this kind have us to conclude that the anomalous rotatory dis-ion of tartaric acid and its esters probably nds on an interaction between the hydroxylic *ogen* and the carboxylic *oxygen*, giving rise to nal co-ordination-compounds such as



s conclusion is in harmony with the fact that the malous dispersion of tartaric acid persists in its rs, *in spite of the elimination of the carboxylic rogens*, which are essential to Astbury's hypo-is; it also agrees with the fact that all the malies disappear in the methylene ether (Austin Carpenter, 1924) in which the hydroxylic hydro-es (but not the carboxylic hydrogens) have been inated.

f, as may be gathered from his letter in NATURE of y 26, Astbury is anxious to lay stress on the fact t the forces which produce anomalous rotatory ersion in solutions of tartaric acid are identical h "the forces which bind the molecules into the rstalline structure," we should be in complete eement with him; but we should regard these es as depending on the simultaneous attraction a proton for two oxygens, rather than of two itons for one another.

Spiral and Structureless Nebulæ.

N "Our Astronomical Column" of NATURE of Agust 2, reference is made to Prof. Perrine's letter o Prof. Lindemann's spiral nebula hypothesis which ppeared in the *Observatory* for July. As Prof. Lidemann's hypothesis was based to some extent o photographic observations of my own, perhaps I may be permitted to make a few comments on the matter generally.

Prof. Perrine's criticisms on the supposed reflection of light from the Galaxy are not new, and are practically covered by my paper on Prof. Lindemann's theory which appeared in the Monthly Notices of the R.A.S. for May last year. The observational facts are entirely against this part of the hypothesis, and I think I am not misrepresenting Prof. Lindemann when I say that he does not attach so much importance to the *source* of reflection as to the probability of reflection being the cause of the colour distribution. There are considerably more grounds for assigning the source of reflection (if any) to the bright central nucleus of the spiral itself. I found, for example, that the curve of light distribution in the nucleus of the Andromeda nebula (N.G.C. 224) was a near approach to the curve $(x+1)^2y = \text{constant}$; and Hubble has recently derived much the same result for a series of bright amorphous ellipsoidal nebulæ of non-galactic type, which have been photographed with the 100-inch reflector at Mt. Wilson. This applies to the amorphous or uncondensed type of spiral nuclei, but it does not apply to the condensed type of spirals where numerous condensations appear and the nucleus is weakened by continued outflow of matter along the spiral arms. In the latter case the peak of the curve is considerably flattened, and the non-luminous matter at the periphery of the nebula is taken up into the condensations.

It may be inferred from this that reflection as a cause of illumination is a possibility in the amorphous type but is definitely ruled out in the condensed type. This has led me to doubt the validity of the photographic observations on which Prof. Lindemann's hypothesis was based. The photographs which Prof. Seares obtained at Mt. Wilson with the 60-inch reflector were comparative—one with an unscreened ordinary plate and the other with a yellow screen and an isochromatic plate. These showed quite definitely for the condensed type a stronger image of the nucleus in the isochromatic than in the ordinary plate compared with the outer regions of the spiral, the inference being that outer regions of the spirals are deficient in the longer wave-lengths. The same results were found in my photographs of the uncondensed type which were measured with a photo-micrometer, and were also carried down to the red region of the spectrum with panchromatic plates and suitable screens. Some photographs were also obtained of the nucleus of the Andromeda nebula with ordinary plates and a nickel oxide screen to cut out the visual part of the spectrum and transmit the ultra-violet. It is evident, however, that we are dealing with plates having contrast factors which differ with the wave-length, and the variation found may be owing to a combination between the range of spectrum and the plate employed.

This question has been dealt with at some length by Ross (*Astrophysical Journal*, vol. 52, p. 86), who finds that the variation of γ (the contrast factor) along the spectrum is greatest for panchromatic plates and least for orthochromatic plates. He points out also that the depth of image in the ultra-violet is not so great as in the longer wave-lengths, which penetrate further into the emulsion. At the same time, I should not wish to condemn the observations out of hand as untrustworthy, but rather I would advocate the repetition of them under more rigorous conditions, which is quite possible, and would give us definite information on this important point.

The Production of very Intense Magnetic Fields.

In a letter to NATURE which appeared in the issue for April 19 last, I gave a brief outline of a method for producing very intense magnetic fields.

I have now made some measurements which show that magnetic fields of considerably greater intensity may be generated by this method than had appeared at first sight to be practicable. For example, in one test a magnetising solenoid wound with 25·5 turns per cm. was used, and the first peak value of the discharge current obtained when condensers of 700 micro-farads total capacity were used, charged to a pressure of 1850 volts, was found from the oscillograph record to be 12,500 amperes. *This means that an intensity of magnetic field of about* 400,000 *gauss was generated.*

By means of a modification of the apparatus which is now being effected, it is expected that an intensity of magnetic field of about 1,500,000 gauss will be obtained very shortly.

It is useful to examine what considerations govern

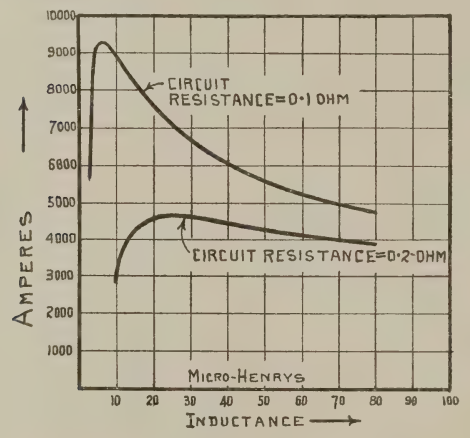

FIG. 1.

the maximum value of the condenser discharge current which can be obtained by this method. The magnitude of the first peak of the discharge current is given by the expression

$$\frac{V}{L\sqrt{\left|\frac{1}{LC}-\frac{1}{4}\frac{R^2}{L^2}\right|}}e^{-\frac{1}{2}\frac{R}{L}T} \text{ amperes,}$$

where

V volts is the pressure to which the condenser is charged.
L henry is the inductance of the circuit.
C farad is the total condenser capacity.
R ohm is the resistance of the circuit.
T second is the time for a quarter-period of the discharge current.
$e = 2{\cdot}718$ and is the base of natural logarithms.

In Fig. 1 the magnitude of the first peak of the discharge current is shown as a function of the inductance when the condenser capacity is 700 micro-farads and the pressure 2000 volts. Two cases have been selected, namely, (i.) for a circuit resistance of 0·1 ohm, and (ii.) for a circuit resistance of 0·2 ohm.

It is important to observe that the maximum value of the first peak of the discharge current is obtained for a definite value of the inductance, and that this maximum value is more sharply defined the smaller the resistance of the circuit. T. F. WALL.

Absorption of Vapours of Various Liquids by Cotton.

THE familiar absorption of water from the air cotton has been studied in our laboratories for so years from various aspects. The phenomena valuable as clues for interpreting the physico-chem structure of cotton cellulose; and in this connexi we have naturally examined the capillary hypothe using Anderson's formula for calculation of capill radii. We recently initiated a simple series observations which indicate that this hypothesis inadequate, by showing that the weight of vap absorbed is dependent on the chemical nature of t vapour, with a suggestion that there is a consta " low level " group, including definite types of liqui with which the values are due to simpler causes th with water or acetic acid, the values for the two lat being far higher. As the differences for vari liquids are very marked and do not seem to ha been previously recorded, the following particul may be of interest, in spite of the primitive meth used in what was merely a preliminary examinatio

Samples of unbleached and bleached twof Egyptian cotton hosiery yarn were suspended, at ro temperatures, in a bottle, in the bottom of which w a layer of the liquid under consideration. The cott (which before enclosure had been dried for four ho in a water oven and then weighed) was withdraw with suitable precautions, at intervals of seve hours and weighed in a weighing bottle. Curves w drawn through the plottings of these weight-values order to show approximately the variation of weig with time for water, alcohol, acetic acid, benze nitrobenzene, carbon disulphide, ether and aceto The following table shows only the saturation val at room temperatures:

Liquid.	Unbleached.	Bleached.
	Per cent.	Per cent.
Water	18 to 20	19 to 21
Glacial acetic acid	18 ,, 20	17 ,, 19
Absolute alcohol	3 ,, 3½	8½ ,, 9
Carbon disulphide	1½ ,, 2	1½ ,, 2
Benzene	1½ ,, 2	1 ,, 2
Ether	7 ,, 7½	7 ,, 7½
Nitrobenzene	1½ ,, 2	1½ ,, 2
Acetone	2 ,, 2½	6½ ,, 7

It is intended to investigate these phenome further in the Experimental Department of the F Cotton Spinners' and Doublers' Association, to wh I am indebted for permission to publish this note.

The Magnetic Resolution of the Scandium Line

SEVERAL lines of the scandium spectrum have be classified by Catalán (An. Soc. Esp., 20, 606, 19 and 21, 464, 1923). According to him, the Sc spectrum contains a doublet- and a quartet-te system; the Sc II. spectrum a triplet-system. It however, probable that some corrections must made in his term-scheme. These corrections obviously also made by Gieseler and Grotrian (*Natur* 12, 438, 1924).

We have made provisional measurements of t magnetic resolution of some scandium-lines. means of the formulæ given by Landé (*Zeit. f. Phy*

[illegible]39, 1923), it has been possible to calculate the [illegible]er part of these resolution patterns from the [illegible]ted term-scheme. The observations agree com[illegible]ely with the calculations on the assumption that [illegible]rdinary formula for the "separation factor" g [illegible]ndé is valid.

[illegible]e observations of a few other lines make it not [illegible]obable, however, that there may be some terms [illegible]hich the ordinary formula does not apply. It [illegible]ds also, from some earlier observations of Rybar [illegible]ik. Zeit.*, 12, 889, 1911) on the related triplet [illegible]rum of lanthanum, that terms with ordinary [illegible]olution and terms with unusual resolution are both [illegible]nt.

[illegible]cording to Landé (*Zeit. f. Phys.*, 17, 292, 1923) [illegible]rdinary g-formula is only valid if in the atomic [illegible]t—that is, the atom without the emitting electron—[illegible]e electrons of the groups with azimuthal quantum [illegible]mbers greater than one form closed configurations [illegible]thout moment of momentum.

[illegible]e neutral scandium atom contains, according to [illegible]h, one single 3_3-electron. The observed separation [illegible]rms show that this single 3_3-electron generally [illegible]ot be present in the atomic rest of the excited [illegible]calium atom, for it cannot be arranged in a closed [illegible]nfiguration. Therefore, it must be the emitting [illegible]ron. The term-scheme really shows that the [illegible]west energy level is a d-term, and this is also con[illegible]rmed by the absorption experiments of Gieseler and [illegible]rian (*l.c.*). In the ionised scandium atom, there [illegible]n 3_3-electron at all, or it must be also in this case [illegible]e emitting electron. The lowest energy level of [illegible]. is not yet known.

It should be noted, however, that the facts obtained [illegible]t the spectra of vanadium and titanium (Gieseler [illegible]cGrotrian, *l.c.*) show that the term-type deter[illegible]ined by means of the term structure and the [illegible]agnetic resolution is not always (perhaps through [illegible]e simultaneous action of different outer electrons) [illegible]one we expect according to the known atomic [illegible]ructure. It may be possible that something of this [illegible]n also happens here.

P. ZEEMAN.

[illegible]msterdam, August 20.

Congenital Eye Anomalies in Albino Mice.

[illegible]ll papers published in the *Journal of Experimental Zoology* (vol. xxvi., 1918, p. 65, and xxxi., 1920, p. 171) [illegible]uyer and Smith have given an account of the trans[illegible]ission, through successive generations, of eye defects [illegible]ich occurred in the offspring of rabbits and mice [illegible]jected, while pregnant, with lens-sensitised fowl [illegible]um. The greater part of the papers concerns [illegible]experiments carried out with albino rabbits, and in [illegible]hat case alone was the question of heredity con[illegible]sidered, but the nature of the defects in both cases [illegible]appears to have been the same.

[illegible]mong a large number of albino white mice which [illegible]roeing bred in this Laboratory, a few have appeared [illegible]recently with abnormal eyes. These have arisen in [illegible]the course of ordinary breeding. The eyes follow in [illegible]appearance the description given by Guyer and Smith; [illegible]they are sometimes reduced in size, and one or both [illegible]eyes are opaque, so that they are of a colourless, [illegible]milky hue instead of the normal red of the albino. [illegible]So far the abnormality has been noticed in about [illegible]4 per cent. of the mice that have been dealt with, [illegible]and while it is at present too early to assert that the [illegible]defect is definitely hereditary, the evidence available [illegible]suggests that this is so.

I should be very interested to hear whether any [illegible]others who have been breeding mice have observed this same abnormality. Guyer and Smith could obtain no information from breeders of similar defects arising naturally in *rabbits*, and concluded that "rabbits are stable forms wholly unlikely to develop eye defects unless, as in our work, these have been deliberately induced by the experimenter." It would appear that as regards albino mice, outwardly similar defects may arise without being deliberately induced, which seems to be a fact of some importance having regard to the bearing of Guyer and Smith's experiments on the problem of the inheritance of acquired characters.

The Stark Effect on Fundamental (Bergman) Series.

ACCORDING to the Bohr theory, we should expect that the Stark effect would be strong in the fundamental (Bergman) series. So far as I am aware, the experimental evidence has not been brought forward, as the lines belonging to this series usually appear in the infra-red region. In a paper published by Saunders (*Astrophys. Jour.*, 52, p. 265, 1920) a certain number of calcium lines in the visible and ultra-violet region are ascribed to the fundamental series.

On referring to my previous work with Mr. N. Kokubu (Mem. Coll. of Sci., Kyoto, 3, p. 173, 1918), I find that many of these fundamental series lines are shifted toward the red by an electric field, as shown in the following table.

	Fundamental triplets $(1d)-(mf)$.				Fundamental Singlets $(1D)-(mF)$.		
m	λ in A	Shifts (for E = 68 kilovolt/cm.)		m	λ in A	Shifts (for E = 68 kilovolt/cm.)	
1	4586·1 81·7 78·8	Not measured		1	4878·3	Not measured	
		p-component	s-component			p-component	s-component
2	4098·8	2·7 A	1·2 A	2	4355·4	4·3 A	2·8 A
	95·3	2·3 A	1·5 A				
	92·9	2·2 A	1·4 A				

On meeting Prof. Saunders at Toronto during the sessions of the British Association, he suggested that this fact might be worthy of mention.

T. TAKAMINE.

Photographs of Lightning.

I AM at present engaged in investigating the forms assumed by lightning flashes in different circumstances and for this purpose require to examine as many photographs of lightning as possible. May I appeal to readers of NATURE who have such photographs to be good enough to give me an opportunity of inspecting them? It is not necessary that the photographs should be technically good; any photographs showing the form of the flash will be valuable. I should like especially to see photographs showing flashes from the tops and sides of clouds.

All photographs will be returned, if required, as soon as they have been examined.

Present-day Problems in Crop Production.[1]

By Sir E. JOHN RUSSELL, F.R.S.

COMPLEXITY OF THE PROBLEM.

THE agricultural investigator is confronted with three closely interlocking agencies—the plant, the climate, and the soil—each of which is variable within certain limits, and each playing a large part in the crop production which it is his business to study.

Confronted with a problem of this degree of complexity there are two methods of procedure: the empirical method of field observations and experiments, in which there is no pretence of great refinement and no expectation that the same result will ever be obtained twice, it being sufficient if over an average of numerous trials a result is obtained more often than would be expected from the laws of chance; and the scientific method, in which the factors are carefully analysed and their effects studied quantitatively; a synthesis is then attempted, and efforts are made to reconstruct the whole chain of processes and results. The scientific method is, of course, the one to which we are naturally attracted. But common truthfulness compels one to admit that up to the present the greatest advances in the actual production of crops have been effected by the empirical method, and not infrequently by men who are really artists rather than men of science, in that they are guided by some intuitive process which they cannot explain, and that they have the vision of the result before they obtain it, which the scientific man commonly has not.

The best hope for the future lies in the combination of the empirical and the scientific methods. This is steadily being accomplished by the recent strong infusion of science into the art of field experimentation, which has much enhanced the value of the field work and the trustworthiness of its results. Modern methods of replication, such as have been worked out at Rothamsted, and in the United States by Harris of the Carnegie Trust (Cold Spring Harbor), Kiesselbach in Nebraska, Myers and Love of Cornell, and others, constitute a marked improvement in plot technique. The figures themselves, besides being more accurate, can be made to yield more information than was formerly the case.

Great advances have been made in the methods of analysing the results. The figures are never the same in any two seasons, since the climatic conditions profoundly affect the yields. A few men, like J. H. Gilbert, have the faculty of extracting a great deal of information from a vast table of figures, but in the main even the trained scientific worker can make very little of them. The reason is that he has been brought up to deal with cases where only one factor is varying, while the growth of plants involves the interaction of three variable factors: the plant, the soil, and the climate. It is impossible to apply in the field the ordinary methods of the scientific investigator where single factors alone are studied; very different methods are needed, adapted to the case where several factors vary simultaneously.

Fortunately for agricultural science, statisticians have in recent years worked out methods of this kind, and these are being modified and developed by R. A. Fish and Miss Mackenzie for application to the Rothamst field data. It so happens that this material is ve suitable for the purpose, since a large number of t field experiments have been repeated every year f seventy or eighty years on the same crop and on t same piece of land, using the same methods; t field workers also remain the same for many years, t changes being rare and without break in continuit Although the statistical investigation is only recent begun, mathematical expression has already been giv to the relationship between rainfall and yield of whe and barley under different fertiliser treatments, a precision has been given to some of the ideas that ha hitherto been only general impressions. If on average of years a farmer is liable to a certain distrib tion of rainfall, it is becoming possible to advise as fertiliser treatment which enables the plant to ma the best of this rainfall.

ALTERATIONS IN THE PLANT.

It is a commonplace among farmers that certa soil conditions influence not only the yield but also t quality of crops. The leaf and root are more eas affected than the seed. The case of mangolds has be investigated at Rothamsted; the sugar content of t root, an important factor in determining feeding val was increased by increasing the supply of potassium the crop. Middleton at Cockle Park showed that gr increased in feeding value—quite apart from any incre in quantity—when treated with phosphates. Potat are considerably influenced by manuring; increasi the supply of potassium influences the composition the tubers and also that much more impalpable qual —the cook's estimate of the value of the potat while we have found at Rothamsted that a high-cl cook discriminated between potatoes fertilised w sulphate of potash and those fertilised with muriate potash, giving preference to the former.

Grain is more difficult to alter by changes in vironmental conditions; indeed, it appears that t plant tends to produce seed of substantially the sa composition whatever its treatment—with the i portant exception of variation in moisture supply. Shutt has explored the possibilities of altering t character of the wheat grain by varying the conditions, and finds that increases in soil moist decrease the nitrogen in the grain. Similar resu have been obtained in the United States.

On the other hand, in England the reverse seems hold, at any rate for barley. This crop is being fu investigated at the present time under the resea scheme of the Institute of Brewing, because of importance in the preparation of what is still Britai national beverage. Increased moisture supply creases the percentage of nitrogen in the grain, and also does increased nitrogen supply, though to a mu less extent; on the other hand, both potassic a phosphatic fertilisers may decrease the percentage nitrogen, though they do not always do so; the la regulating their action are unknown to us.

[1] From the presidential address delivered to Section M (Agriculture) of the British Association, Toronto, August 11.

The practical importance of these problems of regulating the composition of the plant lies in the fact that the farmer can control his fertiliser supply, and to some extent his moisture supply, so that it lies within his power to effect some change should he wish to do so.

In agricultural science one sometimes thinks only of the crop and the factors that affect its growth. But in agricultural practice there is often another partner in the concern: a pest or parasite causing disease. The amount of damage done by pests and diseases to agricultural crops is astounding; in Britain it is probably at least 10 per cent. of the total value of the crops and the loss is probably some 12,000,000*l.* sterling per annum; in some countries it is considerably more. Indeed, the number of insect pests and of harmful fungi and bacteria that skilled entomologists and mycologists have found in our fields might almost lead us to despair of ever raising a single crop, but fortunately the young plant, like the human child, grows up in spite of the vast number of possible deaths. The saving fact seems to be that the pest does harm only when three sets of conditions happen to occur together: the pest must be present in the attacking state; the plant must be in a sufficiently receptive state; and the conditions must be favourable to the development of the pest. It is because this favourable conjunction of conditions comes but rarely that crops manage to survive; and this gives us the key to control if only we knew how to use it. Complete control of any of these three conditions would end all plant diseases. Unfortunately, control is never complete even in glasshouse culture, still less out of doors. But even partial control would be very helpful. All these pests go through life cycles, which are being studied in great detail all over the world, and especially in the United States. Somewhere there occurs a stage which is weaker or more easily controlled than others, and the pest would become harmless if the chain could be broken here or if the cycle could be sufficiently retarded to give the plant a chance of passing the susceptible stage before it is attacked.

The plants themselves, as we have just seen, are in some degree under control, and if they could be pushed through the susceptible stages before the pest was ready, they would escape attack. Barley in England is sometimes considerably injured by the gout fly (*Chlorops tæniopus*). The larvæ emerge in spring from the eggs laid on the leaves and invariably crawl downwards, entering the young ear if, as usually happens, it still remains ensheathed in leaves. J. G. H. Frew, at Rothamsted, has shown that early sowing and suitable manuring cause the ear to grow quickly above the track of the larvæ, and thus to escape injury. E. A. Andrews, in India, has found that tea bushes well supplied with potassic fertiliser escape attack from the mosquito bug (Helopeltis) for the rest of the season, apparently because bushes so treated become unsuitable as food to the pest. Further, the conditions are alterable. H. H. King, in the Sudan, has effected some degree of control of the cotton thrips (*Heliothrips indicus*) by giving the plant protection against the drying north wind and so maintaining a rather more humid atmosphere—a condition in which the plant flourishes more than the pest. Tomatoes in England suffered greatly from Verticillium wilt until it was found that a small alteration of temperature threw the attack out of joint. They are also much affected by stripe disease (*B. lathyri*), but they become more resistant when the supply of potash is increased relative to the nitrogen. It has recently been maintained, though the proof is not yet sufficient, that an altered method of cultivating wheat in England will afford a good protection against bunt. These cultural methods of dealing with plant diseases and pests offer great possibilities, and a close study jointly by plant physiologists and pathologists of the responses of the plant to its surroundings, and the relationships between the physiological conditions of the plant and the attacks of its various parasites, would undoubtedly yield results of great value for the control of plant diseases. Again, however, the plant breeder can save a world of trouble by producing a variety resistant to the disease; or there may fortunately be found an immune plant from which stocks can be had, as in the case of the potatoes found by Mr. Gough to be immune to the terrible wart disease.

Control of Environmental Factors.

It thus appears that, if only plant breeders and plant physiologists could learn to alter existing plants or to build up new plants in such a way that they should be well adapted to existing soil and climate conditions, and not adapted to receive disease organisms at the time the organisms are ready to come—if only they could do this, all agricultural land would become fertile and plant diseases and pests would become ineffective: at any rate until the pests adapted themselves to the new plants. Although no one can set limits to the possibilities of plant breeding and plant physiology, we cannot assume that we are anywhere near this desirable achievement or that we are likely to be in our time.

There will always remain the necessity for altering the environmental conditions to bring them closer to the optimum conditions for the growth of the plant. No attempt is yet made in the field to control two of the most important of the factors: the light and the temperature, though it is being tried experimentally. There is a great field for future workers here; at present plants utilise only a fraction of the radiant energy they receive. At Rothamsted attempts have been made by F. G. Gregory to measure this fraction; the difficulties are considerable, but the evidence shows that our most efficient plants lag far behind our worst motor-cars when regarded as energy transformers for human purposes. One hundred years ago the efficiency of an engine as a transformer of energy was about 2 per cent.; now, as a result of scientific developments, it is more than 30 per cent. To-day the efficiency of the best field crops in England as transformers of the sun's energy is about 1 per cent.:[2] can we hope for a similar development in the next hundred years? If such an increase could be obtained an ordinary crop of wheat would be about 400 bushels per acre, and farmers would feel sorry for themselves if they obtained only 200 bushels. But we are only at the beginning of the subject. Increases in plant growth amounting to some

[2] The remaining energy being largely used up in transpiration. This figure refers to the total radiation received by the leaf, and not to the fraction received by the chloroplast surface. For this latter the value is much higher.

20 or 25 per cent. have been obtained by V. H. Blackman in England under the influence of the high-tension electric discharge, which presumably acts by increasing in some way the efficiency of the plant as an energy transformer. Possibly other ways could be found. It needs only a small change in efficiency to produce a large increase in yield. Much could be learned from a study of the mass of data which could be accumulated if agricultural investigators would express their results in energy units as well as in crop yields as at present.

Interesting results may be expected from the attempts now being made in glasshouse culture both in Germany and at Cheshunt to increase the rate of plant growth by increasing the concentration of the carbon dioxide in the atmosphere.

Control of the Soil Factors.

The soil factors lend themselves more readily to control and much has been already achieved. Water supply was one of the first to be dealt with. Civilisation arose in the dry regions of the earth, and so far back as 5000 years ago, irrigation was so advanced as a practical method that it came into the ordinances drawn up by the great Babylonian king Hammurabi. The chief problems at the present time are to discover effective means of economising water and to ascertain, and if possible control, the relationships between the soil, the water, and the dissolved substances in the water.

Inseparably bound up with water supply are the questions of cultivation and of drainage, which affect not only the water but the air supply to the roots. The former subject is now attracting considerable attention: the great need is to discover means for expressing cultivation in exact physical and engineering units. The measurements of Keen and Haines at Rothamsted, and the chemical work of A. F. Joseph, N. Comber, and others on clay, and of Odén, Page, and others on humus, indicate the possibility of finding exact expressions and of effecting co-operation with the workers in the new fields of agricultural engineering.

Another soil factor which readily lends itself to some degree of control is the amount of plant nutrients present. The possibility of increasing this by means of manure has been so frequently explored in field trials that it has sometimes been regarded as almost a completed story; indeed, Rothamsted tradition affirms that Lawes himself once gave orders to have the Broadbalk field experiments discontinued because they had nothing further to tell; it was only the earnest persuasion of Gilbert that caused him to countermand the order. So far from the subject being exhausted, it still bristles with problems. The new nitrogenous fertilisers, resulting from War-time activities in nitrogen fixation; the need for reducing the cost of superphosphate; the change in character of basic slag; and the Alsatian development in potash production, are producing changes in the fertiliser industry the full effects of which are not easy to foresee. Economic pressure is driving the farmer to derive the maximum benefit from his expenditure on fertilisers, lime, farmyard manure, and other ameliorating agents, and is compelling a more careful study of possibilities hitherto disregarded, such as the use of magnesium salts, silicates, and sulphur as fertilisers, and, above all, a much more precise diagnosis of soil deficiencies than was thought necessary in pre-War days.

There are, however, more fundamental problems awaiting solution. It is by no means certain that we know even yet all the plant nutrients. The list compiled by Sachs many years ago includes all needed in relatively large amounts, but Gabriel Bertrand has shown that it is not complete and that certain substances—he studied especially manganese—are essential, although only in very small amounts. Miss Katherine Warington, working with Dr. Brenchley at Rothamsted, has shown that leguminous plants fail to develop in the so-called complete culture solution unless a trace of boric acid is added. Mazé has indicated other elements needed in small amounts.

Another problem needing elucidation is the relationship between the quantity of nutrients supplied and the amount of dry matter produced. Is dry matter production simply proportional to nutrient supply, as Liebig argued, with the tailing off beyond a certain point, as demonstrated by Lawes and Gilbert, or is it always less than this, as indicated by Mitscherlich's logarithmic curve; or is the relationship expressed by one of the more complex sigmoid curves as there is some reason to suppose? We do not know; and the problem is by no means simple, yet it governs the "diminishing returns" about which farmers now hear so much.

Again, very little is known of the relationship between nutrition and the period of growth of a plant. One and the same quantity of a nitrogenous fertiliser, for example, may have very different effects on the plant according as it is given early or late in life; not only is there a difference in quantity of growth, but also in the character of the growth. Late dressings cause the characteristic dark-green colour to appear late in the season, and thus affect the liability to fungoid diseases; they increase the percentage of nitrogen in the grain and they may give larger increases of crop than early dressings.

Investigations are needed to find the best methods of increasing the supply of organic matter in the soil and its value for the different crops in the rotation.

All these problems will sooner or later find some solution. But there remains a greater problem of more importance than any of them: the linking-up of plant nutrition studies with those of the soil solution. As our cousins in the United States were the first to emphasise, the fundamental agent in the nutrition of the plant is the soil solution, and they have made a remarkable series of investigations into what appeared at one time a hopeless proposition—the physico-chemical interactions between the soil and the soil water. A great advance in crop production may be expected when the soil chemists have discovered the laws governing the soil solution, when the plant physiologists can give definite expression to the plant's response to nutrients, and when some one is able to put these results together and show how to alter the soil solution so that it may produce the maximum effect on the plant at the particular time. The new soil chemistry will yet have its triumphs.

The Soil Micro-organisms.

It is now more than forty years since the discovery of the great importance of micro-organisms in determining soil fertility. Practical applications necessarily lag far behind; but already three have been made each of which opens out great possibilities for the future. The long-standing problem of inoculation of leguminous crops with their appropriate organisms has already been solved in one or two of its simple cases, chiefly lucerne in new land, and the new process has helped in the remarkable extension of the lucerne crop in the United States and in Denmark. We believe at Rothamsted that the more difficult English problem is now solved also. Interesting possibilities are opened up by the observation that a preliminary crop of Bokhara clover seems to facilitate the growth of the lucerne.

The organisms effecting decomposition are now coming under control, and are being made to convert straw into farmyard manure (or a material very much like it) without the use of a single farm animal. The process was worked out at Rothamsted, and is being developed by the Adco Syndicate, which is now operating it on a large scale and is already converting some thousands of tons of straw annually into good manure.

The third direction in which control of the soil organisms is being attempted is by partial sterilisation. This process is much used in the glasshouse industry in England, and it has led to considerable increases in crop yields. The older method was to use heat as the partial sterilising agent, and this still remains the most effective, but owing to its costliness, efforts have been made to replace it by chemicals. Considerable success has been attained; we have now found a number of substances which seem promising. Some of these are by-products of coal industries; others, such as chlor- and nitro-derivatives of benzene or cresol, are producible as crude intermediates in the dye industry.

The Need for Fuller Co-operation.

Looking back over the list of problems it will be seen that they are all too complex to be completely solved by any single worker. Problems of crop production need the co-operation of agriculturists, plant physiologists, soil investigators, and statisticians. Even plant breeding necessitates the help of a physiologist who can specify just what the breeder should aim at producing. This gives the key-note to the period of agricultural science on which we have now entered—it is becoming more and more a period of co-operation between men viewing the problem from different points of view. Good individual work will of course always continue to be done, but the future will undoubtedly see a great expansion of team work such as we know from our experience at Rothamsted is capable of giving admirable results in agricultural science.

With fuller co-operation both of men and of institutions we could do much to overcome the present difficulty in regard to utilising the information we already possess. In the last thirty years an immense stock of knowledge has been obtained as to soils and crops. It is stored in great numbers of volumes which line the shelves of our libraries, and there much of it rests undisturbed in dignified oblivion. In the main it consists of single threads followed out more or less carefully; only rarely does some more gifted worker show something of the great pattern which the threads compose. But even the most gifted can see but little of the design; the best hope of seeing more is to induce people to work in groups of two or three, each trained in a different school and therefore looking at the problem from a different point; each seeing something hidden from the rest. Unlike art, science lends itself to this kind of team work; art is purely an individual interpretation of Nature while science aims at a faithful description of Nature, all humanistic interpretation being eliminated. There is certainly sufficient good will among the leaders of agricultural science to justify the hope of co-operation; there are probably in existence foundations which would furnish the financial aid.

This leads to my last point. What is the purpose of it all? Team work, co-operation, the great expenditure of time and money now being incurred in agricultural science and experiment—these are justified only if the end is worthy of the effort. The nineteenth century took the view that agricultural science was justified only in so far as it was useful. That view we now believe to be too narrow. The practical purpose is of course essential; the station must help the farmer in his daily difficulties—which again necessitates co-operation, this time between the practical grower and the scientific worker. But history has shown that institutions and investigators that tie themselves down to purely practical problems do not get very far; all experience proves that the safest way of making advances, even for purely practical purposes, is to leave the investigator unfettered. Our declared aim at Rothamsted is "to discover the principles underlying the great facts of agriculture and to put the knowledge thus gained into a form in which it can be used by teachers, experts, and farmers for the upraising of country life and the improvement of the standard of farming."

This wider purpose gives the investigator full latitude, and it justifies an investigation whether the results will be immediately useful or not—so long as they are trustworthy. For the upraising of country life necessitates a higher standard of education for the countryman; and education based on the wonderful book of Nature which lies open for all to read if they but could. How many farmers know anything about the remarkable structure of the soil they till, of its fascinating history, of the teeming population of living organisms that dwell in its dark recesses; of the wonderful wheel of life in which the plant takes up simple substances and in some mysterious way fashions them into foods for men and animals and packs them with energy drawn out of the sunlight—energy which enables us to move and work, to drive engines, motor-cars, and all the other complex agencies of modern civilisation? No one knows much of these things; but if we knew more, and could tell it as it deserves to be told, we should have a story that would make the wildest romance of human imagination seem dull by comparison and would dispel for ever the illusion that the country is a dull place to live in. Agricultural science must be judged not only by its material achievements, but also by its success in revealing to the countryman something of the wonder and the mystery of the great open spaces in which he dwells.

Recent Work at Stonehenge.

By Lieut.-Col. WILLIAM HAWLEY.

CONSIDERABLE progress has been made during the last two years in the work of excavation which is being carried out at the site of Stonehenge, and although nothing giving any clue to the age and purpose of the monument has yet been discovered, many places in the area surrounding it have yielded matter of much interest and importance.

In order to find out the conditions of the Avenue and its relation to the place, an excavation of the ditch around the circular rampart was begun about 40 feet from where it would approach the south bank of the Avenue. The ditch was 6 feet deep where digging began, suddenly rising soon afterwards to a level 3 feet higher, but gradually returning to nearly the former depth as it went onwards. When the line of the Avenue bank was reached, there was no trace of it meeting the ditch, which passed on for about 25 feet beyond the spot and ended against a very upright bank of solid chalk about 5 feet high, widening and taking a roughly circular form with a flat bottom. An excavation, in the line of the ditch, made about 50 feet beyond this obstruction revealed a similar solid side. The intervening portion, which was 40 feet wide, proved to be a causeway of natural chalk which crossed the ditch and afforded an entrance to the circular enclosure. The ending of the ditch on the west was roughly circular like that on the east side, but here it formed a large wide pit 7½ feet deep communicating with another beyond it through a narrow opening. Both bore traces of fires at the bottom, and scattered around them were horn picks, bones of animals, and quantities of flint flakes.

The surface of the causeway was very remarkable as it was studded with 58 holes, more or less in regular lines, occupying the entire length and width of it. These were probably of the same age as the ditch, and with it seem to have been for defence and resisting combined attack, pointing to the place in its early history being one of defence.

In the entrance and in line with the rampart crest a large stone hole was found close to another previously excavated, the latter being the one the "Slaughter" stone is thought to have stood in.

Excavation afterwards included the portion of the Avenue between the entrance and the fence at the high road. The small side banks and ditches of it begin 10 feet from the main ditch, showing that the Avenue was independent of it and probably of later construction. Formerly it was believed that the Avenue entered Stonehenge, but it is now seen that the actual entrance was over the causeway, mentioned above, and only about half as wide. The Avenue is 70 feet wide where it begins, but the ditches are irregular in their alignment, carelessly dug, and of a variable depth of about 3 feet.

The ditches have a layer of silt upon the bottom, reaching half-way up, which contains nothing of the Stonehenge period, but the stratum over it does, so it might be inferred from this that the Avenue preceded Stonehenge by a considerable interval. Evidence of the Stonehenge period is gained from a stratum which varies from an inch or two to 15 inches in depth and is distributed with very fair evenness over the whol surface of the place. It contains the mason's chip and things that belong to and after that period alon and therefore is a most useful guide for determinin periods which precede and those which follow after th making of the monument, helping also to show that i is of Neolithic age. It has been necessary to mak this digression in order that the context may be mor clearly understood.

There were two large holes found near the Helestone and there can be little doubt that they once hel stones, and their filling of loose chalk was that whic fell back when they were extracted. Over one of them there was a dump of nearly four thousand sarse chippings and sandy debris, showing that a stone ha been dressed on the spot, and no doubt taken from th hole and, after preparation, used for the monument It seems from this that there may have been a certai number of rough sarsens already *in situ* here befor Stonehenge was built. Each of the stones was 40 fee from the Helestone and suggest that a little grou might have stood there independently of anything tha might have been standing within the circle at the time

A trench 4 feet wide was found around the Helestone but only a part was excavated, as the remainder i covered by the high road. Like the small ditches, i had been half filled with silt, which had chips in th filling over it, but not in it, thus showing an earlie origin than Stonehenge.

Three large post holes occurred westward from the Helestone, with distances equally divided. They resembled those on the causeway and were certainly of early date, as the Avenue bank on the west covered two of them. The remainder of the Avenue was quite barren of anything of interest and had been much eroded by a medieval coach road and country traffic.

Excavation was afterwards transferred to the interior of the circular enclosure, and a systematic search began of the land within by cutting trenches in close succession over it from the rampart nearly up to the standing stones. Last year 107 trenches were opened and the N.E. quadrant accounted for, and this year it is hoped to complete the S.E. quadrant. The trenches were mostly over shallow ground and, on the whole, not very productive, but some of them certainly afforded places giving much information and interest.

The first line of trenches was directed towards the entrance at the standing stones, and, after proceeding a little way, holes were come to of a sharply cut, rectangular, oblong form, measuring about 5 feet long by 3 feet wide at the top, tapering in a wedge shape to a narrow bottom. These were found to extend in a regular succession in two rows around the outer circle, the holes of each new circle being exactly opposite standing stones. It was afterwards ascertained by sounding that similar cavities exist around the present outer circle, indicating that there were once two extra circles to the monument. For the sake of reference they have been called Y and Z circles. The first holes of the former began at 38 feet from the standing stones, and the latter 10 feet distant. Their side intervals are

rular but they are not concentric with the standing
le nor in relation to themselves. The distance from
outer circle gradually diminishes from where they
in at the entrance until No. 8 is reached, after
ich they take up the original distance; this applies
both circles. Some confusion was noted where the
egularities terminated; No. 7 hole had been only
rtly dug, and Z8 was found not to exist.

It can be clearly proved that these holes were made
the Stonehenge period, because the mason's chips
re present in the filling and even upon the bottom.
e first four holes excavated occur in the fairway
m the entrance, and it may be safely said that they
ver held stones. Although dug for the purpose,
nsideration afterwards led them to leave the holes
npty, as the stones would have been inconvenient in
e fairway. Their sharpness and undisturbed con-
ion showed there had been no insertion and extrac-
n of stones; moreover, one of them contained five
g antlers and another a single antler, showing
sence of stones. The other holes showed disturb-
ces caused by extracting stones. Soil had fallen
ck, partly filling the holes, and over it was a more
cent stratum bearing objects from the time of
traction to the present day. Romano-British
jects were found in the upper stratum, and in one
le, about 18 to 20 inches from the top, there was
rty soil mixed with wood ashes and some natural
nts arranged apparently as a temporary hearth, and
the same level were 42 pieces of a Romano-British
t. A little below this level were three pieces of fine,
itty pottery belonging to the "La Tene" period.
his gives the impression that the stone was extracted
that time, and that spoliation on the site might
ve begun quite an early date.

Where the irregularity occurred at No. 8, a con-
derable area was opened out to try to discover a
ason for it, but with not much success. A great
any post holes were met with, and, since then, a still
reater number have been found extending from this
ot towards the rampart, some of them taking the
rm of parallel lines; these are now in course of
vestigation. They are evidently of quite early date,
s the Stonehenge stratum passes over them and they
ntain nothing of that period. Eleven of them, about
6 feet apart, formed a long row, the last two holes at one end having been united by digging to form a grave at a time when posts no longer stood there, the holes and loose matter affording less trouble in digging one. A skeleton found in it proved to be that of a person belonging to a long-headed race existing shortly before the Roman occupation. Owing to insufficient length and capacity of the grave (barely 3 feet deep) the remains were much crushed, but have nevertheless been reconstructed.

Remains of the Bronze age do not occur until after the erection of Stonehenge and are found in the upper stratum consisting chiefly of foot-worn fragments of pottery. With a cremation of that period there was found a beautifully ground and polished mace head of the "cushion" type. The stone is hornblendic gneiss and probably came from Brittany. Eight other specimens are known to exist of that type, now in collections, five of them coming from Scotland and three from the Thames and its neighbourhood, and they are regarded as ceremonial maces of that period. With another cremation a very fine bone pin 7 inches long was found. It had been burnt with the body and was much twisted by heat and broken in three places, but was easily mended. The cremated remains are usually found but a short distance below ground, most of them actually without cists in the loose chalk rubble at the foot of the rampart; sometimes the remains are found clinging to a turf when it is cut and turned over. This shows that the rampart conditions cannot have been very different then from what we see them now. The impression created during the continuance of excavation here makes one aware that a long succession of events is being dealt with which have covered a vast number of years. The silting of the main ditch alone is a proof of this. This process must have taken a very long time, for sometimes there are 6 feet of it and not a vestige of the Stonehenge era occurs in it, and is only met with as a narrow stratum below the turf and abruptly divided from it. Unfortunately, none of these matters have as yet given any information as to the date of the monument, but there is yet a great deal of ground to be opened, and by more time and diligent search it is hoped eventually to arrive at some clear conclusions.

Circumnavigation of the Earth by Aeroplane.

ON April 6, four U.S.A. aeroplanes left Seattle on an air voyage of circumnavigation of the world. Five months later, on September 6, two out of the four arrived at Boston. Flying took place on 48 days out of 153 days thus consumed. The actual flying hours were 288; the distance covered was 21,500 miles. About every third day on the average was therefore a flying day of 6 hours flying at 75 miles per hour, giving a flying day's run of 450 miles.

The flight falls naturally into four stages, floats being fitted for stages 1 and 3, wheels for 2 and 4. New engines were fitted at the start, and in Japan, at Calcutta, and at Hull. New wings were fitted at Calcutta, and numerous subsidiary repairs and replacements were carried out. Cruisers, supply ships, and flotillas of destroyers were employed in the improvised organisation along the sea routes. Existing permanent organisations were available along the land routes.

In stage 1 the route runs along the Pacific Coast of Canada and Alaska, and crosses the northern entrance of the Pacific Ocean by the Aleutian Islands; thence it runs by Kamchatka and Japan round the Chinese and Burmese coast to Calcutta. The Aleutian Islands, in which aeroplane No. 1 fell out, are subject to fogs, squalls and blizzards, the Chinese seas to typhoons, and the southern arc, Saigon—Rangoon, to tropical heats. There is no permanent airway organisation in the first part of this stage, and in the second part the Japanese, French and British organisations are not continuous. In this stage as a whole, flying took place only on 22 days out of 82, 11,000 miles being covered in 158 flying hours.

At Calcutta 4 days were spent in fitting new engines, new wings, and wheels for the overland stage Calcutta—

London. Leaving Calcutta on July 1 and arriving at Hull on July 17, the aeroplanes flew on 15 days out of 17, covering a distance of 6500 miles in 74 flying hours. The advantage of a permanent ground organisation is evident, and to this is added the inherent advantage of wheels over floats in both weight and air resistance.

At Hull 11 days were spent in overhauling the aeroplanes and in fitting new engines, and floats for the passage of the northern entrance of the Atlantic by way of the Orkneys, Faroë Islands, Iceland, Greenland and Labrador. Leaving Hull on July 30, and arriving at Boston on September 6, the aeroplanes flew on 11 days out of 39, 4000 miles being covered in 56 flying hours. Aeroplane No. 3 fell out between the Orkneys and Iceland. The remaining stage is from Boston via New York to Washington, thence due west to Salt Lake City, and so back to Seattle. Fitted with wheels, and using a homogeneous national air organisation, there is high probability that the two surviving aeroplanes will complete expeditiously the circumnavigation of the earth by air except in so far as they are detained by the hospitality of their countrymen at the landing places.

In drawing technical conclusions from the flight, no account can be taken of the great personal effort of the pilots and mechanics in thus facing successfully every sort of condition along 24,000 miles of route, unknown to them. The quasi-sporting condition that the same aeroplane bodies should circle the earth albeit with new engines, wings and other parts is also irrelevant. In a strictly utilitarian organisation fresh machines and pilots familiar with the route would be available for each 5-hour stage, and two such stages a day would be feasible. When it is found possible to maintain permanent airway organisation along such regions as the northern entrances of the Atlantic and Pacific Oceans, it may become possible, flying 10 hours a day at 100 miles per hour, to circumnavigate the world by air in about 24 days as a matter of routine travelling.

Obituary.

Mr. Hartley Lupton.

BY the death on September 6 of Mr. Hartley Lupton, at the early age of thirty-two years, physiology has lost a research worker of great industry and promise, his pupils a teacher who won their respect by his care and keenness and their affection by his simplicity and kindness, his friends at Manchester and at University College, London, a generous and devoted colleague. For generosity, simplicity, and devotion were the keynotes of Lupton's life. Stricken with a fatal illness in June, he spoke continually of returning to his beloved apparatus in a few weeks. Only a month before his death, at a time of great discomfort and distress, he read with appreciation and delight the manuscripts of three papers shortly to appear in the Proceedings of the Royal Society, describing the results of three years of devoted work. Rarely, until his last illness had completely incapacitated him, was he absent from the laboratory: he arrived first in the morning, he left last at night; he was always ready for any new experiment, any new enterprise, any extra work.

Lupton had an extraordinary capacity for friendship with young men, a capacity which served him well as a tutor at Dalton Hall, Manchester, and later in his physiological research work, where he continually needed "subjects" for his experiments. All who knew him will recall the pleasant and humorous picture of Lupton engaged in some experiment on severe muscular work, either on himself or some friend whom he had induced to take (at any rate temporarily) a sufficient interest in physiology to act as the subject of his—often rather strenuous—experiments. His own personal devotion can be gauged from the frequent entry "Subject, H. L. postabsorptive" in his records.

Lupton obtained a first-class honours degree in physics at the University of Manchester: the outlook of the physicist remained with him in his later work, and led to the scrupulous accuracy which is seen in all the records of his observations. His first independent scientific task was the routine work with radium at the Manchester Royal Infirmary. His experience there led his questioning mind to ask for the reason why radioactive bodies should have the effect they do on living tissues: the next step was to decide to take a medical degree, and it was as a student of physiology that the present writer first made his acquaintance. His teachers soon realised that Lupton was a person of rather singular interests and capacity, and an early opportunity occurred of starting him on physiological research. Working for the Medical Research Council, he took up the study of muscular exercise in man, based on the results of recent investigations of the isolated muscle. The subject proved fertile beyond expectation, and the results of it are contained in several papers published in the *Quarterly Journal of Medicine*, the *Journal of Physiology*, and the Proceedings of the Royal Society. When he began this work, three years ago, little was known of the connexion between the physiology of the muscle and that of human muscular exercise. Three years of continual labour—years probably the happiest of his life, for he was never so happy as when "going all out"—have discovered and explored a new subject, the important one of the recovery process after muscular effort in man. To the physiological world the subject will remain, one may hope, associated with his name: to his colleagues it will always recall the unceasing devotion and the simple kindness of their friend. A. V. H.

Prof. B. I. Slovzov, professor of biochemistry in the University of Saratov, and later in the Medical School for Women, Petrograd, whose death is announced, was a pupil of A. Kossel and A. Danilevsky and is known mainly for his contributions to the study of tissue enzymes. Another Russian man of science who has died recently is Prof. N. P. Kravkov, professor of pharmacology in the Medical Academy, Petrograd. Prof. Kravkov was a pupil of Schmiedeberg, and his chief work was performed on isolated organs which he used mainly for investigating the action of drugs upon blood-vessels. His method of the isolated rabbit's ears for testing vasoconstrictor and vasodilator substances is known universally and used in every pharmacological laboratory. Lately he contributed interesting observations upon the coronaries of the human heart and the isolated human fingers. He had been interested in the past few years in the action of drugs in highly diluted solutions.

Current Topics and Events.

WE are glad to learn that Mr. Jowett, First Commissioner of Works, has now definitely refused to permit the sect of Latter-Day Druids, or "Church of the Universal Bond," to make use of Stonehenge for the burial of the ashes of their dead. In a letter to Lrd Crawford, Mr. Jowett says, "I have decided that under no circumstances can any burials be permitted within the precincts of Stonehenge in the future." When the proposed desecration of the national monument became known, strong protests were raised against it, and in our issue of September 6, p. 364, we expressed the resentment generally felt in regard to the claims and intentions of the sect which contemplated such action. It would probably be difficult to prevent members of the sect from scattering ashes of certain of their dead members within Stonehenge, but we assume that no formal assembly for this purpose will be authorised. In his reply to a question in the House of Commons in July, Mr. Jowett said that no objection would be raised to the use of the national monument for the proposed burial of such ashes, provided that there was "no serious disturbance of the ground," and the sect announced that no such disturbance was intended, as there would be "nothing in the nature of an interment." It is not yet clear whether the sect may hold a service within the precincts of Stonehenge and formally scatter the ashes of their dead upon the ground.

AN interesting event took place at the house of the Royal Photographic Society, 35 Russell Square, on Saturday afternoon, September 13, when a memorial tablet to William Henry Fox Talbot was unveiled in the Library by Dr. G. H. Rodman, a past president of the Society. A distinguished company included Miss M. Talbot and Mrs. Stewart, grand-daughters of the distinguished investigator whose memory was honoured. Dr. Rodman, after referring to the historical collection of experimental apparatus used by Fox Talbot and presented by Miss M. Talbot to the Museum of the Royal Photographic Society, reviewed Talbot's photographic researches, which appear to have been commenced in 1834. In that year, on the lines of Schutze, Scheele, and Wedgwood, Talbot produced sun prints of lace and leaves on paper treated with silver nitrate and sodium chloride; in 1835 he secured an image on moist sensitised paper in the camera obscura on a bright day with an exposure of ten minutes. The results of his researches were communicated in 1839 to the Royal Society in two famous papers on photogenic drawing. In 1840, by the use of paper impregnated with silver iodide and gallo nitrate of silver, Talbot secured results in ten seconds. The process, which he termed the calotype process, was patented in 1841 after a means had been found to obtain positive prints from the negatives. Dr. Rodman paid an eloquent tribute to the value of Fox Talbot's contribution to science through these researches, upon which the modern practice of photography is based. The memorial, by Messrs. George and Fred Hawkings, consists of a finely modelled portrait of Fox Talbot, executed in bronze, with decorative surroundings upon a marble background, and bears the inscription—"William Henry Fox Talbot, 1800–1877. This Memorial was erected by public subscription of photographers, 1922."

THREE years ago, the Notgemeinschaft der Deutschen Wissenschaft was formed for co-ordinating all help received in Germany for the learned staffs of universities, technical high schools, and other institutions. The third report of this society has been issued and can be obtained from the offices situated in the Schloss, the former residence of the Kaiser, Berlin, C2 Schloss, Portal 3. It seems that 1923–4 was a year of very real need indeed; the period lasting until November 1923, when a very adverse rate of exchange existed, making foreign purchases impossible, was followed by a period of great want of money, making not only foreign but also internal purchases difficult. In 1923, the Reichstag made three grants of money, although it was not in a position to pay immediately. The most valuable of these was made in October and consisted of 500,000 gold marks (approx. 27,000*l*.). It was not possible to continue the programme of buying the most important journals published during the War until the fall in the mark had ceased. The sum of 46,000 gold marks (2500*l*.) was expended on the libraries of 23 universities, 11 technical high schools, and 300 larger institutions. Twenty-five copies of the Paris *Comptes rendus* had to supply all these institutions. Foreign periodicals were cut down to one-fortieth of pre-War supply, and journals in covers were circulated for two months at a time to the individual universities. It was only possible to buy sixty foreign books of average value 15 marks, for each institution, but this number was increased by gifts from Switzerland, Sweden, Norway, U.S.A., Spain, and Great Britain. During this period it was possible to publish 117 periodicals and 103 books in all fields of knowledge on the funds of the association. Many German firms helped the funds by providing apparatus for special researches. Hajime Hoshi, of Japan, provides 2000 yen monthly for the period of three years for chemical research. The General Electric Company of America provided 12,500 dollars, to which German electrical firms added 1250 dollars, for electrophysical research under a committee consisting of Planck, Laue, Franck, Haber, Nernst, and Wien. In all faculties it was possible to make grants to 100 people of 25 to 100 dollars for special researches and journeys. It is hoped that the financial situation this next twelve months will be such that Germany will be able to buy foreign periodicals and books and resume the international exchange of academic thought.

THE low temperature carbonisation of coal excites at the present time the widest interest. The intelligent member of the general public hears much of it as a solution of the smoke problem and that of the supply of liquid fuel. The truth is often difficult

to get, especially by those desirous of appraising the validity of inventors' claims. The information conveyed in a circular just issued by the Department of Scientific and Industrial Research will therefore attract widespread interest. The offer is made that the Fuel Research Staff of the Department will undertake to test, without fee, approved plant and processes for low temperature carbonisation, under certain conditions. Application must be made on forms obtainable at the offices of the Department, 16 Old Queen Street, Westminster, S.W.1. The gist of the conditions may be summarised as follows. Applicants are to furnish full information and facilities for prior inspection by officers of the Department to permit of a decision as to the justifiability of a test. If undertaken, the test will be made under the supervision of a member of the Fuel Research Staff. Applicants will have to provide all requisite facilities, including material, staff, labour and measuring instruments, considered necessary. Applicants may be represented during the test, but the decision as to duration and conduct of the test will rest with the officer of the Fuel Research Staff supervising. The Department reserves to itself the right to publish a report on the results of tests made.

NOT the least important of the departmental exhibits in the British Government Pavilion at the British Empire Exhibition, Wembley, is that illustrating the work of the Imperial Institute in promoting the use of little-known or new raw materials of the Empire. The exhibit directs attention to the principal branches of the Institute—the scientific and technical department, the technical information bureau, and the exhibition galleries—and illustrates by series of specimens and publications the nature of the work carried out by the departments and technical committees. A collection of British Empire timbers includes samples of little-known woods recommended for use in Great Britain by the Timbers Committee of the Institute and fully tested in the timber laboratory. The fibre exhibits include samples of cottons from Irak and Tanganyika, and an important exhibit of silk cocoons, reeled and thrown silk and fabrics woven therefrom, illustrates the endeavours of the Institute's Silk Committee to extend the production of raw silk within the British Empire. There is an interesting display of new materials suitable for paper-making, and of papers made from them. The investigations of plantation rubber, carried out in connexion with the Ceylon Rubber Research Scheme, are also illustrated. Other sections relate to the work on oil-seeds, essential oils, tobaccos, resins, tanning materials, and drugs; and there is a collection of economic minerals including tropical African coals; materials for pottery, brick, and cement manufacture, illustrated by specimens of products made from them at the Institute; and radio-active and other minerals. A free pamphlet describing the exhibits and the departments of the Institute has been issued and may be obtained at Wembley, or on application to the Director, Imperial Institute, London, S.W.7.

WE have received from Messrs. Thomas Firth and Sons, Ltd., a statement containing some of the essential features of their exhibit at the Britis Empire Exhibition. A very wide range of produc has been gathered together. Firth's stainless steel now so well known amongst engineers that conside able attention will doubtless be focussed on th branch of their manufactures. A selection of man different types of turbine blading is shown, includir twelve blades removed from a 2000 KW. Westing house turbine (steam pressure 200 lb., superhe 200° F.). Nine of these are of 5 per cent nickel stee the remainder are of Firth's stainless steel. Th actual hours run were 12,809 in six cases and 29,98 in the remainder. All the nickel steel blades sho very marked signs of erosion, being very rough an pitted; the edges also show distinct signs of frayin Those which have given longest service are quit worn out. The stainless steel blades, on the othe hand, are as bright and as unaffected as the day c which they were inserted; the edges retain the initial sharpness and no signs of wear are apparen anywhere. Turbine engineers will doubtless tak note of this remarkable difference in properties. pump rod of similar steel which has been in use i an ammoniacal liquor pump is also shown. The li of carbon steel rods is never more than about si months. The stainless steel rod is worn only abou $\frac{5}{64}$ths of an inch. Moreover the surface is smoot and polished and not badly scored as it is in the cas of carbon steel rods. A rake end is shown which ha been in use in a roasting furnace for treating zin concentrates containing 28-30 per cent. of sulphu This has already been in use for three months, where the total life of a similar article made of mild steel only three weeks. Various other products are show which indicate the superior service given by Firth stainless steel.

THE *Weather Map* of the meteorological service o the Dominion of Canada for July has recently bee received. It shows the mean temperature and th total precipitation for the month, and graphicall the difference of temperature from the normal an the comparative amount of rain over the whole o Canada. Part of July was exceedingly hot i southern British Columbia and very warm in th North-western Provinces. There was a deficienc of temperature amounting to 4° F. or more in easter Manitoba, northern Ontario, and north-easter Quebec. The precipitation varied considerably i different parts. The Edmonton district of Albert and parts of Manitoba, as well as the northern coas of the Pacific, received from 4 to 6 inches or mor of rain; some regions in Quebec had more tha 5 inches. In the maritime provinces the gener average was less than 2 inches. On the souther coast line of Nova Scotia, moisture from abundan fogs mitigated to some extent the drought, whe rivers and streams are said to be very low and wel are drying up. At the back of the *Weather Ma* the highest and lowest temperatures and the pr cipitation, with brief comments on the weath and the state of the crops, are given for eac station, the latter being of considerable intere generally.

THE first conference of the Pathological and Bacteriological Laboratory Assistants' Association was held on September 1-5, in the Department of Pathology of the University of Edinburgh. The attendance was exceedingly good, there being members present from all parts of Great Britain and also from Africa. The local organisation was in the hands of a committee appointed by the Scottish Division of the Association. Lectures and demonstrations in laboratory technique were held, an exhibition of laboratory work and apparatus was on view, and places of interest in and round Edinburgh were visited. Members of the Scottish Division of the Association were responsible for the exhibition, while the London Division showed objects of tropical interest and demonstrated specimens illustrating the life history of parasites and their insect hosts. At the dinner on Friday evening, September 5, the president, Prof. A. E. Boycott, made the presentation of the first Woodhead medal to Mr. Albert Norman together with an address. This medal has been established by means of funds collected among members of the Association in memory of the late Sir German Sims Woodhead. In all, 141*l.* has now been received and the subscription list is soon to be closed. According to the regulations governing the award which have now been drawn up, it is to consist of a prize and medal, the former being open to members of the Association only. Awards may be made annually or at longer intervals at the discretion of the Memorial Committee.

IT is stated in *Science* that Dr. E. S. Dana, emeritus professor of physics and curator of mineralogy at Yale University, has been elected a corresponding member of the Vienna Academy of Sciences.

APPLICATIONS are invited from honours graduates in physics or electrical engineering for two junior assistantships in the National Physical Laboratory, Teddington. The necessary form of application may be had from the Director of the Laboratory, and returned to him not later than September 27.

THE autumn presidential address to the Radio Society of Great Britain will be delivered at 6 o'clock on Wednesday next, September 24, at the Institution of Electrical Engineers, by Prof. W. H. Eccles, who will deal with the latest developments of the position of the scientific amateur under the Wireless Telegraphy Regulations.

THE twenty-first anniversary of the School Nature Study Union will be celebrated on Saturday, September 27, in the Common Rooms of the London Day Training College, Southampton Row, High Holborn. There will be a reception by the president, Dr. P. Chalmers Mitchell, and an address by Mr. G. H. Gater, Education Officer, London County Council. The general secretary of the Union is Mr. H. E. Turner, 1 Grosvenor Park, Camberwell, London, S.E.5.

APPLICATIONS are invited for appointments as temporary assistant chemists at the Government Laboratory. Candidates must possess the degree of B.Sc., with not less than second-class honours or equivalent, and should have, if possible, experience in investigative work. A form of application is obtainable from the Government Chemist, Clement's Inn Passage, W.C.2. The latest date for its return is September 30.

THE twenty-eighth autumn fungus foray of the British Mycological Society will be held at Bettws-y-Coed, N. Wales, on September 22-27. Mr. J. Ramsbottom will deliver his presidential address, entitled "The Taxonomy of Fungi," on September 24. Other papers to be read at the meeting are by Dr. Harold Wager on an aldehyde reaction in the tissues of fungi, and by Mr. A. W. Bartlett on a new species of Urophlyctis producing galls on *Lotus corniculatus*. Particulars of the foray can be obtained from the General Secretary of the Society, British Museum (Natural History), London, S.W.7.

THE Riga correspondent of the *Times*, in a message dated September 12, states that news had been received from Moscow announcing the arrival at Urga, Mongolia, of Mr. Roy Chapman Andrews, leader of the Third Asiatic Expedition of the American Museum of Natural History, who is seeking permission for the exploring and excavating work which it is proposed to carry out in 1925. This seems to dispose of the fears which were entertained in New York as to Mr. Andrews' safety. It was known there that he was on his way from Peking to Urga, and some anxiety was felt in view of the political disturbances which have been reported recently in Urga.

A LARGE individual of the loggerhead turtle, a tropical and sub-tropical species, was found alive near Dunvegan, Skye, on December 13, 1923. In recording its occurrence (*Scottish Naturalist*, 1924, p. 99) Dr. James Ritchie states that it measured 4 ft. 5 in. in length, weighed 309 lb., and was a female. It contained more than 1000 eggs, and is being mounted for exhibition in the Royal Scottish Museum, Edinburgh. Previous occurrences of the loggerhead turtle in Scotland date back to 1861, when two or perhaps three young specimens were found on the mainland about the same time; a small individual, recently dead, was washed up on North Uist in 1898.

THE British Research Association for the Woollen and Worsted Industries announces the following awards for the year 1924–25: Research fellowships to Mr. R. Burgess, of Nottingham, to enable him to continue his research at the University College, Nottingham, on the bacteriology and mycology of wool; and to Mr. J. E. Nichols, of Edinburgh, to conduct research at the Animal Breeding Research Department of the University of Edinburgh on the relationships between the wool fibres of various breeds of sheep: an advanced scholarship to Mr. H. Maldwyn Williams, tenable at the Scottish Woollen Technical College, Galashiels.

THE following awards for the year 1924–25 have been made by the Salters' Institute of Industrial Chemistry and approved by the Court of the Company:—Fellowships are renewed to Dr. W. G. Sedgwick, Armstrong College, Newcastle-on-Tyne, and Oxford, Fellow, 1923–24, and to Mr. W. Randerson,

Imperial College of Science and Technology, Fellow, 1922–23, and Hon. Fellow, 1923–24 (during tenure of Albert Kahn Travelling Fellowship). Fellowships are awarded to Mr. H. H. Evers, University of Liverpool; Mr. K. Knight Law, University College, Nottingham; Mr. H. S. Pink, University College, Nottingham, and Oxford; and Mr. V. E. Yarsley, Birmingham University. The Salters' Institute has also awarded seventy-two grants in aid to young men and women, employed in chemical works in and near London, to facilitate their future studies.

DURING the forthcoming winter, Mr. H. V. Garner, the guide demonstrator of the Rothamsted Experimental Station, Harpenden, will be available for lectures to Chambers of Agriculture and Horticulture, Farmers' Clubs, Agricultural Societies, etc., on the Rothamsted experiments in regard to the manuring of various crops, the management of farmyard manure, and on chalking and liming. For Students' Societies and similar bodies, lectures could be arranged dealing with the field and laboratory work at Rothamsted. No fee is charged for Mr. Garner's services, but any association engaging him would be expected to defray travelling expenses. All communications regarding lectures should be addressed to the Secretary, Rothamsted Experimental Station, Harpenden.

THE next meeting of the American Association for the Advancement of Science is to be held at Washington on December 29–January 3, and local committees have been appointed. Great efforts are being made to deal with the question of wide publicity for the meeting. Authors of papers are being asked to prepare abstracts of their contributions, and Science Service is again to co-operate with the Association's publicity committee in preparing material for the Press. The meeting will open with the address of the retiring president, Dr. C. D. Walcott, and it is hoped that the President of the United States will also address the Association and the associated societies. Another general meeting will be held on December 31, when Prof. A. S. Eddington will speak on "Relativity." In connexion with the meeting, an exhibition of scientific apparatus, methods, books, and products is being arranged as in previous years. Reduced railway fares have been arranged for members of the Association travelling to Washington from any part of the United States, or from places in Canada east of and including Armstrong, Fort William, and Sault Ste. Marie, Ont.

A DIRECTOR of research is required for the Forest Products Research Laboratories of the Department of Scientific and Industrial Research which are being provided to deal with pure and applied scientific research called for by the practical needs of the using industries and departments of state. The researches will be specially concerned with home-grown and Empire-grown timbers and other forest products. Candidates should possess good scientific qualifications, and a broad experience of the origin and use of forest products. Width of knowledge in forest economy, in the technology and practical problems of the wood-using industries, and in the bearing on these problems of scientific and industrial research, is considered of first importance. The latest date for the receipt of applications (which should be sent to the secretary of the department, 16 Old Queen Street, Westminster, S.W.1) is December 1.

Our Astronomical Column.

MERCURY A MORNING STAR.—Mercury will reach its greatest elongation west (17° 52′) on September 27 and be favourably visible as a morning star. The planet may be seen shining over the eastern horizon about an hour before sunrise. Its position will be in Leo, about 28° E.N.E. of the brilliant planet Venus. On the day of its elongation the planet will rise at $4^h\ 12^m$ A.M., G.M.T., or $1^h\ 43^m$ before the sun.

Apart from the morning stars—Mercury and Venus—the zodiacal light will be strongly visible on clear mornings towards the end of September and the beginning of October, when the moon will not offer any impediment to observation.

STUDIES OF ALGOL VARIABLES.—Studies of the details of the light-curves of these variables, combined with spectroscopic measures of their radial velocities, are of importance from the information they give about stellar masses, diameters, and the degree of darkening of their limbs from atmospheric absorption. Mr. R. S. Dugan is undertaking an extensive investigation of their light-curves by photography at Princeton University Observatory. No. 6 of the Contributions of the Observatory contains researches on five variables. SZ Herculis is interesting from the slight degree of limb-darkening, the slight loss of light at secondary minimum, and the considerable masses, 4·6 and 1·4 of the sun, the spectral types being B8, B9. R Canis Majoris is the only naked-eye star among the five, its normal light being 5·3 mag., and the loss of light at primary and secondary minimum, 0·56 and 0·06 respectively. The masses are small: assuming a mass-ratio of 3 to 1, they are 0·14 and 0·05 of the sun; the spectral type of the primary is FO. Two of the five stars, Y Camelop and RY Aquarii, give indications of limb-darkening. The most conspicuous loss of light at secondary minimum is that of SZ Herculis, 0·24 mag., as compared with 1·83 at primary minimum.

ENCKE'S COMET.—Several photographic positions of this comet were obtained in August by Mr. G. Merton with the 30-inch reflector at Greenwich. They indicate that the date of perihelion will be close to Oct. 31·437 G.M.T., which is 0·008 day later than that predicted by L. Matkiewicz. The comet should be an easy telescopic object at the end of September. The following ephemeris by Matkiewicz is for Greenwich noon.

ABORIGINES OF THE MALAY PENINSULA.—In vol. , pt. 1 of the Journal of the Federated Malay States useums, Mr. Ivor H. N. Evans gives an account of an pedition to Mt. Gunong Benom, Pahang, undertaken March and April 1923 for the purpose of verifying statement made by Wilkinson in the 1911 Census eport that "the wild tribes on Gunong Benom spoke distinct dialect of their own . . . and it is not ossible at present to say whether this distinction is companied by any racial or cultural differences." s a result of his investigations, Mr. Evans is doubtful hether the census enumerators visited the mountain induced the inhabitants to come down from it. e himself was unable to find any traces of aborigines of their occupation, and, with the exception of two akai-Jakun, no aborigines were found on the western de. On the way down to Kuala Krau an aboriginal ttlement was reached at Galong, near Kuala Krau, nd the inhabitants there, who were Jakun speaking Sakai dialect, informed him that there were no oorigines on Gunong Benom, though Negritos Batek) of Ulu Cheka visited it to collect Ipoh poison. Ir. Evans also obtained information of two divisions f aborigines on the Lompat river, of whom one, the o-ben, is very wild, lives in shelters, does not cultivate ne soil, and uses stone knives for cutting and splitting ood.

THE ART OF THE PAL EMPIRE IN BENGAL.—In a ommunication to the Royal Society of Arts which is ublished in the Society's Journal of August 22, Mr. . C. French points out that the mounds which mark s buried cities and its art are the only relics we ossess of the Pal dynasty. This dynasty reigned in Bengal from the eighth to the eleventh centuries of ur era, when it was overthrown by the Sena dynasty —an event which marked the decline of Buddhism nd the establishment of a new caste system. The ise of the Pal dynasty with the first king Gopala, lescribed as "sea-born," ended a period of anarchy. The art of this early period was marked by simplicity, lignity, and an immanent sense of life and vitality. In the succeeding reign of Devapala flourished Dhiman and his son Bitpala, the only two artists whose names have been preserved. They founded the Eastern School and the School of Magadha respectively. Early in the eleventh century, Pal art had reached its zenith and began to show signs of decline in its more florid style. In the orthodox Brahmanical period which succeeds the Pal dynasty, the art is harder, stiffer, and more conventional, with over-elaborated decoration. The inspiration of the artistic representation of orthodox Hindu deities in the earlier period would appear to be derived from Buddhism and to have declined with it. The importance of the art of the Pal Empire, notwithstanding its local character, lay in its influence on other, and also on later schools of Indian art.

THE BRACHYCEPHALIC SKULL.—Prof. F. G. Parsons has published the results of his study of the brachycephalic skull by means of dioptographic sketches and by the method of reduction of a series to composite sketches from three points of view, together with the detailed measurements, in the Journal of the Royal Anthropological Institute, vol. 54, Pt. 1. It would appear that the length of the dolichocephalic skull depends upon increased growth in its posterior part, while the greater breadth of the brachycephalic skull is due to growth in its temporal regions. The short European skull is usually more prognathous than the dolichocephalic skull. It is also more broad-nosed, and its orbital height is not so great when compared with the whole area of the face. Both as regards width and height, the orbital measurement would appear to be of considerable racial importance; in the Nordic race the orbit is very high, while in both the Mediterranean and the Long Barrow races it is very low. In the brachycephals it comes between, but is closer to the Long Barrow race than to the Nordic.

THE GREAT BARRIER REEF.—The first report of the Great Barrier Reef Committee of the Royal Geographical Society of Australasia is published in the Queensland *Geographical Journal* (vol. xxxviii.). The work of investigation included in this report was mainly of a general nature, but it indicates some of the problems which it is hoped to solve. Attention was particularly devoted to those parts of the reef between Cairns and Thursday Island. Attention paid to the form and size of cays and reefs fully confirmed previous ideas as to the influence of the prevailing south-east wind in developing the forms of coral debris along stream lines more or less parallel to the direction of the wind. Observation did not confirm the contention of Agassiz that "nigger heads" are proof of recent elevation. It appears more likely that the occurrence of these masses of coral is due to the action of hurricanes which tear off portions of the growing reef and wash them to leeward. Another problem of great interest is the origin of the openings through the outer Barrier. The committee discards the theory that these openings mark old entrances to the sea of the present coastal rivers. The evidence rather points to their being coastal valleys of the foundered strip on the edge of which now exists the Great Barrier Reef, although many of the drowned valleys have been silted up to a considerable extent. The sediment from the coastal streams being deposited in the depths of the drowned regions, prevents coral growth in these areas.

GEOCHEMICAL DISTRIBUTION OF THE ELEMENTS.—The distribution of the elements in the earth, considered from the geochemical point of view, is the subject of a series of three papers issued recently by Prof. V. M. Goldschmidt, of Christiania, under the title "Geochemische Verteilungsgesetze der Elemente" (Videnskapsselskapets Skrifter, I., Mat.-Naturv. Klasse; 1923, No. 3; 1924, Nos. 4 and 5.) He regards the earth as having been originally gaseous or molten. On cooling, it passed through a stage in which there were three fluid phases consisting of metal, sulphide and silicate. These three different kinds of molten material separated according to gravity, giving a concentric arrangement, with the metal at the core, next a shell of sulphide matter, and outside this a shell of silicate, around which there was a cover of vapour and gas. The silicate shell separated by crystallisation into heavier and lighter parts, gases escaping from it in the process. In accordance with this supposed differentiation of the materials of the earth into four phases during the process of cooling, he divides the chemical elements into four corresponding main groups, namely, (1) siderophils (Fe, Ni, Co, P, C, Mo, Pt, etc.); (2) chalcophils (S, Fe, Cu, Zn, Cd, Pb, As, Sb, Bi, Ag, Au, Hg, Pd, etc.); (3) lithophils (O, Si, Ti, Zr, Th, F, Cl, Br, I, B, Al, Y, La, Ce, Li, Na, K, Be, Mg, Ca, Sr, Ba, V, Cr, Mn, Nb, W, Sn, etc.); and (4) atmophils (H, N, He, Ne, A, etc.). A further separation of the elements is effected by later differentiation in the lithosphere, during the course of which any residual chalcophils aggregate as sulphide deposits, while

residual atmophils find their way into the atmosphere. According to their isomorphic relationships with the commoner lithophils, the rarer lithophils can be divided into three sub-groups, namely, (1) elements of the first crystallisation, isomorphic with trivalent iron and magnesium, *e.g.* chromium, vanadium, and nickel; (2) elements of the chief crystallisation, isomorphic with potassium, calcium and aluminium, *e.g.* rubidium, strontium and in part scandium; (3) elements of the residual crystallisation, which are non-isomorphic or only weakly isomorphic with the commoner lithophils, *e.g.* lithium in part, boron, niobium, thorium and lanthanum. In the second paper Prof. Goldschmidt deals with the geochemical distribution of the elements in relation to the structure of the atom, while in the third paper he deals with the distribution of the rare-earth metals among minerals.

Weather in West Indies.—A summary of the weather in the West Indies and surrounding neighbourhood for 1923, prepared by Mr. Oliver L. Fassig, Meteorologist in Charge, has recently been published under the superintendence of the Weather Bureau of the U.S. Department of Agriculture. The rainfall was generally deficient, and the annual total was between 25 and 35 per cent. below the normal in Jamaica, Santo Domingo, and Porto Rico of the Greater Antilles, and Dominica and Martinique of the Lesser Antilles. In Porto Rico the total for 1923, 51·63 in., was the smallest recorded in the past 25 years. Rainfall was continuously below normal, over the section as a whole, from January to September and in November. For the three consecutive years—1921, 1922, and 1923—the aggregate deficiencies in rainfall for the area as a whole amounted to 40 inches, and rainfall above the normal was recorded only in 8 months out of 36. Although 1923 was exceptionally dry, October was conspicuous for the frequency of torrential rains. Temperatures during the year were generally slightly above the normal for the area as a whole. The region of the West Indies and Caribbean Sea was remarkably free from cyclonic disturbances. A few errors have crept in, and among those noticed are the statement in the general summary, p. 97, that the October temperature was below the normal; the month clearly should be April. On p. 105 the sea-water temperature at Balbao in the Panama Canal Zone for August is given as 93·1° F., which is clearly 10° too high, and the March temperature given as 69·3° is presumably 10° too low. Monthly Reports are regularly published, based on a large number of observations. These contain, in addition to the ordinary meteorological observations, details of earthquakes which are not summarised in the Annual Report.

Insectan Palæontology.—Entomologists have been following with keen interest Dr. R. J. Tillyard's series of papers on the Mesozoic Insects of Queensland, appearing since 1916 in the Proceedings of the Linnean Society of New South Wales. In his latest contribution to the subject (*l.c.* xlvii. pt. 4) Dr. Tillyard describes further insect remains from the Upper Trias of Ipswich, Queensland. These include a Protorthopteron apparently allied to members of the Upper Carboniferous fauna of Europe, as well as several species of Orthoptera, Odonata, Hemiptera, Neuroptera, and Coleoptera. Among the Hemiptera, both Homoptera and Heteroptera are included, the most noteworthy discovery being a new genus, Triassocoris, belonging to the Cryptocerata—that section of the bugs which comprises our familiar Nepa (water-scorpion) and Notonecta (water-boatman), as well as the large tropical Belostomatidæ to which Triassocoris, though smaller, is nearly allied. In another paper (*l.c.* pt. 3) Dr. Tillyard describes some Permian insects collected at Belmont, New South Wales, by Mr. J. Mitchell. These fossils are of very great importance, as they prove that the late Palæozoic Australian insect fauna included metabolic insects belonging to the living orders of the Mecoptera and the Neuroptera Planipennia, as well as to the extinct Paramecoptera. Dr. Tillyard suggests that this ancient assemblage of insects was part of "a fauna developed in association with the fern *Glossopteris*, in which primitive scorpion-flies took the place of the cockroaches dominant in the Carboniferous and Permian of the Northern Hemisphere." He comments on the comparatively high organisation of these oldest known Australian insects, believing that they immigrated into that region long after the more primitive types had been established in the European area. Two recent short papers by Dr. Tillyard are of interest on account of the remarkable conditions under which the insect-wings described were found. A long-horn grasshopper, probably of late Tertiary age, is represented by a wing-fragment embedded in a large crystal of selenite, enclosed in the actual copper lode worked by the Mount Elliott mine, North Queensland (*Rec. Geol. Soc. N.S. Wales*, x. pt. 2). A new genus of dragon-fly is described (*Geol. Mag.* lx., 1923, No. 706) from wing-fragments discovered by Mr. R. May, of Cambridge, in the matrix of the shell-cavity of an ammonite of Upper Jurassic (Corallian) age, which, washed out of its proper bed, was found in the Boulder Clay of Hertfordshire.

Mechanism of Photosynthesis.—Jaroslav Peklo (*Chem. News*, 129, 1924, pp. 91-94) recently advocates the adoption of Willstätter's scheme as to the rôle of catalase in photosynthesis. The arguments are based on the effect of potassium cyanide on the rate of liberation of oxygen in photosynthesis. This substance (and also hydrogen sulphide and phenylhydrazine) exerts a paralysing effect on catalase action, but not on all other enzyme reactions. The immediate stoppage of photosynthesis on treatment with potassium cyanide is therefore held to show that catalase takes some intimate part in photosynthesis and hence to prove that Willstätter's view is correct.

Fruit Production in Cacao.—In the *Tropical Agriculturist* (lxiii., 1924, pp. 22-26), Prof. S. C. Harland outlines the results of some interesting experiments in Trinidad on the fruit yield of vegetatively propagated cacao plants. A striking feature of the results is the fact that there is no connexion between the average yield of the parent plants and that of their budded offspring. Thus the practice of taking buds from parents of high fruit-setting power apparently has no experimental justification. The author points out that this result is probably paralleled by similar experiments on apple, cotton, and rubber, and he suggests that the ultimate yield of the budded tree must depend not only on the quality of the buds but also on that of the stock on which they have been incorporated.

A High Vacuum Pump.—Report No. 62 of the Research Department, Woolwich, emanates from the Radiological Section and describes a new glass mercury condensation pump for the production of high vacua, designed by Dr. Gilbert West, which has been in use in the Department for some time and is easy to make and clean. The mercury is contained in a glass flask with a long neck, which is kept cool by a water jacket surrounding it. The upper end of the neck is connected to the auxiliary pump, which provides a pressure between an eighth and a thousandth of an atmosphere. A side tube enters the neck

...e lower end of the cooled portion and is bent ...rds so as to be within the cooling water jacket. ...pper end of this tube is connected to the vessel ... evacuated. The mercury is heated to about ...C., at which it has been found the pump as ...ed gives the best results. The vacua obtain... are only limited by the evolution of gas from ...alls of the vessels evacuated, and the rate of ...cation is high.

METALLURGICAL MICROSCOPES.—A new catalogue ...rice list of metallurgical microscopes, outfits, and ...sories has recently been issued by Messrs. James ...i and Son, Ltd., of 81 Tottenham Court Road, ...on, W.1. The microscopes described have been ...ned specially for metallurgical work, and include ...e well-known Jackson-Blount model and the ...ted Metallurgical Microscope. In the latter, the ...n of which is due to Le Chatelier, the objective ...is upwards and is immediately below the stage ...hich the specimen is placed. By reason of this ...n, the necessity for grinding the object parallel ...ounting it in wax or using a levelling stage is ...ated. The present model is provided with a ...nodious stage and improved focussing adjust... The illuminator fitted to both these types of ...oscopes has a reflector which can be adjusted in ...out across the optic axis and can also be tilted ...ltaneously in two azimuths at right angles to ... other, thus allowing efficient and uniform illu...tion to be obtained. The instruments, optical ...pment, and accessories included in the catalogue ...r the full needs of the metallurgical microscopist ...ged either in regular routine work or in original ...rch.

ELECTRICAL CONDUCTIVITY AND BOHR'S THEORY ...ATOMIC STRUCTURE.—The maximum conductivity ...e elements occurs, according to Vegard, when a ... electron is added to the structure in a new orbit. ...r O. Feussner, in the *Zeitschrift für Physik*, July 12, ...s a table showing the probable electronic structure ...lements which are not included in that of Bohr, ... compares the combined tables with the graph ...wing the connexion of conductivity with atomic ...mber. Maxima are found in the case of the alkali ...als, including cæsium and rubidium, in which a ...le electron circulates in the highest orbit group, ... the configuration of the inner electrons is that of ...h preceding inert gas; there are also maxima for ... Ag, and Au; the relation between the electron ...rits of Cu and the preceding element Ni is assumed ...e as follows:

	1_1	$2_1 2_2$	$3_1 3_2 3_3$	4_1
28 Ni	2	4 4	6 6 6	—
29 Cu	2	4 4	6 6 6	1

...very similar to that between the orbits of potassium ...d argon; a similar relation holds between Ag and ... and the metals which precede them in the table. ...ts true that the same relation holds for Co and the ...ceding element Fe, though Co does not show a ...tive maximum of conductivity. Vanadium is an ...mple of an element with one electron in a 4_1 orbit, ...ich does not show a maximum; it has 12 electrons ...the *M* group, while titanium, the preceding element, ...s 10, and two in the *N* group (4_1); such elements ...w no maximum. Cr, Mo, and W have relative ...xima, though the most probable number of ...ctrons in the orbit group with highest principal ...antum number n is two. It has been suggested ...t an examination of the spark spectrum of Cr ...uld decide whether there are one or two electrons ...the *M* group.

EVIDENCE OF INTRA-ATOMIC FIELDS IN SPECTRA.—The effect of strong electric and magnetic fields on the mercury spectrum has recently been described in a paper by Messrs. Hansen, Takamine, and Werner (Det Kgl. Danske Viden. Sels., Math.-Fys. Medd. v. 3). The primary object of the investigation was to see if the lines, $1S - 2p_1$ and $1S - 2p_3$, which are forbidden by the selection principle, could be produced under magnetic or electric influence. It was found that while the former was excited in considerable intensity by condensed discharge, the latter could not be produced at all. The general effect of the electric field was the production of new combination lines, of which the relative intensities, state of polarisation, and displacements in the fields were measured. The general features of the effects were in close agreement with the quantum theory of spectra. Some time ago Dingle pointed out that the spectrum of the flame-arc of mercury in vacuum contained lines of the type $2p - mp$, which are disallowed by the selection principle, and Takamine, in a further paper (*Japanese Journal of Physics*, vol. ii., Nos. 3-5), surmising that the explanation lay in the close gathering of the atoms in the narrow flame so that the intra-atomic electric fields came into play, describes further experiments with a vacuum arc provided with a constriction. The spectra of mercury, zinc, cadmium and thallium were examined. It was found that, at the constriction, many lines normally forbidden by the selection principle were produced. The similarity between the broadening of the lines at the constriction and that produced in the Stark effect led to the conclusion that the appearance of the forbidden lines was actually a Stark effect due to the intra-molecular electric field coming from the close gathering of ions and electrons at the constriction.

THE IRON SPECTRUM.—In the *Japanese Journal of Physics*, vol. ii., Nos. 1-2, Messrs. Nagaoka and Sugiura describe some interesting investigations of the iron spectrum, made with the view of detecting regularities in the arrangement of the lines. The lines were sorted into groups by observing their behaviour in an electric field, the simplest of the effects thus produced being "the enhancement of lines with small displacement towards shorter wave-lengths." Lines affected in this way were found to form triplets, quartets, sextets, and sometimes more complex groupings, all of which were similar to the Zeeman patterns ordinarily formed by the components of single lines when produced in a magnetic field. This suggested that the lines were actually Zeeman components, produced by the strong intra-atomic magnetic fields of the atoms. The separations in the groups—which varied, in groups of the same type, over a considerable range—amounted in some instances to several hundred units of wave number. For example, there are six quadruplets in which a separation having a mean value of 362·9 occurs: the individual separations range from 354 to 372. From the ordinary expression, $\Delta\nu/H = 4{\cdot}7 \times 10^{-5}$ gauss^{-1} cm.$^{-1}$, this gives, on the assumption mentioned, an intra-atomic field of 7×10^6 gauss—in close agreement with the value deduced by Weiss from his experiments on the magnetic quality of iron at high temperatures. One difficulty facing the hypothesis is the fact that the lines in question are themselves decomposed by an external magnetic field, whereas they would be expected to be merely displaced if they were already magnetically produced components of lines. It is remarked also that sometimes one and the same line enters into several different groups. The authors suggest that the intricate nature of the spectral lines of ferro-magnetic metals may ultimately be traced to the existence of intra-atomic fields.

Food Preservatives and their Action.

UNDER modern conditions of civilisation, the question of supplying food to large numbers of people who live at a distance from the actual areas of production, has assumed an importance which can scarcely be overestimated. The problem has been attacked along two lines: first, by means of quicker and more efficient transport; secondly, by the introduction of preserved foods, including under this term both those which are sterilised by heat and also those preserved by exposure to low temperatures. Owing to the loss or partial destruction of certain accessory food factors during the process of preservation, it is essential that fresh food, especially vegetables and fruit, should be available for general use, and this is largely ensured by means of efficient transport between producer and consumer. On the other hand, certain articles of diet, especially meats, which must be transported long distances, must undergo some treatment to keep them in a condition fit for human consumption, and there is no doubt that the most suitable method to employ is one which ensures sterility and its maintenance during transport: thus the meat, after *efficient* sterilisation by heat, may be tinned and kept sealed from the air, or it may be chilled or frozen, the low temperature preventing any microbic or similar growth.

Unfortunately, simple chilling of meat at a temperature just below freezing point will not prevent deterioration on a long voyage: freezing at a temperature of 10° F. is, however, successful, but the meat does not compare so favourably with fresh meat. It has, therefore, been suggested that the process of chilling might be supplemented by the addition of a chemical preservative or antiseptic when meat has to be conveyed long distances before consumption. The substance which has been used commercially to a small extent in this connexion has been formaldehyde, and the question at once arises as to the effect of this substance upon the human economy. In the Interim Report of the Food Preservatives Committee,[1] recently published, the use of formaldehyde as a food preservative is considered, both from a general point of view and also with particular reference to the carriage of chilled beef. The Committee is unanimous in condemning its use, both with regard to its effects on the consumer himself and also from the fact that it can be used to conceal incipient decomposition without, of course, thereby rendering the food unfit for human consumption.

Formaldehyde acts as an antiseptic since it is a powerful protoplasmic poison: its action is, however, not specific for micro-organisms only, but it also reacts with human tissues, combining with the proteins: thus its excretion is slow and so its action is probably cumulative. When ingested it irritates the mucous membranes with which it comes in contact, and after prolonged use may cause inflammation of the liver and kidneys. It also combines with the proteins of foods, thus rendering them less digestible. In spite of these drawbacks, its use might perhaps have been thought less objectionable in the case of chilled meat, where the carcasses, after being placed in the refrigerating chamber, are exposed for a short time only to the action of the formaldehyde in the form of vapour; the air in the chamber is then circulated by fans, and after about half an hour the vapour is removed by a current of fresh air.

In these circumstances it might have been supposed that any organisms on the surface of the carcass would be killed and the meat remain fresh at the temperature just below the freezing point. Apart from the fact that the process is uncertain in its action owing to the uneven distribution of the vapour in the chamber, its success also seems to depend on the cleanliness with which the meat is handled before it is put into the chamber. These considerations tell against the method, and when it is also found that traces of formaldehyde may be present in the meat at more than one inch from the surface, it is seen that the consumer may take in his system quantities of the poison which cannot fail in the long run at any rate, to be injurious.

The Committee concludes, therefore, that formaldehyde should be banned as a food preservative in all cases. This conclusion may be applied also to the use of formaldehyde as an antiseptic in disease. For external application it has its use, but internally any effect it may have upon micro-organisms is counteracted by its simultaneous deleterious action upon the tissues of the body.

The Free Atmosphere in India.[1]

THE Memoirs before us are by Mr. J. H. Field, who has succeeded Sir Gilbert Walker at Simla, and by Dr. W. A. Harwood. They are of particular interest from the fact that both authors have been connected with upper-air work in England almost from its first conception.

In the introduction, Mr. Field discusses the methods and instruments that were used, many of which were designed by him especially for the purpose; and he is to be congratulated on the success that has been attained.

Owing to the climate of India the ordinary rubber balloons could not be used, on account of the difficulty of storage, and gutta-percha balloons, made up as required, were substituted for them. Mr. Field describes his semi-graphical methods of working up theodolite observations quickly, and gives some very useful formulæ showing the final error in terms of the errors of observation. He finds that too much trust may easily be placed in the two-theodolite method and gives an example in which the four angular measurements are perfectly consistent among themselves and yet the height of the balloon is in error by 50 per cent. He adopted the tail method for general use.

The results of some very useful experiments are given, showing the extent of the errors which may occur owing to the heating by solar radiation of the recording instruments, and also by the inevitable lag of the thermograph. The conclusion reached is that the resulting error is small up to a height of six kilometres, and this is confirmed by the good agreement of the mean values obtained by night and by day. Above 10 kilometres the error is increased by the unfortunate necessity in having to use gutta-percha balloons, the rising velocity of which falls off as their highest point is reached; but up to 12 kilometres it does not seem likely that the error exceeds two or three degrees.

Mr. Field has done a most useful piece of work

[1] "Memoirs of the Indian Meteorological Department." Vol. xxiv., Parts v., vi., vii., and viii.

his memoir should be read and carefully studied by every one similarly engaged: to such it will give many valuable hints.

In Part vi. Dr. Harwood discusses the observations made with kites and registering-balloons over India and the Arabian Sea. He gives first a summary of the results obtained by Field by means of kites, and then deals with the registering-balloon ascents made in India, chiefly at Agra, during the years 1914–18. Of 237 were sent up, 156 instruments were returned, and 152 of these gave usable records, a result which reflects great credit on Mr. Field and his Indian assistants. The figures were handed to Dr. Harwood, on his return from war service in 1918, to be worked up. Dr. Harwood has taken every care to ensure accuracy, and being well acquainted with the many possible sources of error, has only used such ascents as may be reasonably supposed to be free from error, especially from the effects of solar radiation, a precaution needful in view of the slow rise of gutta-percha balloons. He gives particulars of the temperature, humidity, and pressure at various heights in the three Indian seasons—the cool, the hot, and in the monsoon—and also annual means for the density. He carries his tables up to 12 kilometres, and it is only to be regretted that the stratosphere was not reached, and that at least the results from Agra are not published in full detail.

It is not possible to comment on the many interesting points discussed, but the following may be mentioned. The mean annual lapse rate comes out as identical up to 9 kilometres with that of nearly all other stations; so also the daily temperature variation in India, as elsewhere, is confined to the first one or two kilometres. The excessive heat of the hot season is found to be confined to the bottom layer; higher up the monsoon season is the hottest. The high correlation between pressure and temperature is noticeable in Europe is absent in India, perhaps because the short period variations of pressure are too small.

Comment is made on the figures for the equator given by the reviewer in the M.O. Geophysical Memoir, No. 13, and the absence of information as to their source. These figures were formed from the smoothed mean values derived from the few data available at that time. Further observations on the equator are necessary to show whether Van Bemmelen's excellent set of results from Batavia, most of which have been published since then, fairly represent the general equatorial conditions.

Parts vii. and viii. discuss the motion of the free air over India as it is observed by means of clouds and pilot balloons. The year is divided into three seasons, and three separate heights are taken: the height of low clouds, 2 kilometres; of middle clouds, 5 kilometres; and of high clouds, 9 kilometres. These are the heights assigned to the different clouds in the International Cloud Atlas, and Dr. Harwood accepts them as correct for India. Many tables are given showing the direction of the wind and the percentage frequencies for each direction at each height for 15 stations distributed over the Peninsula; in some cases separate values for each month are given. It is noted that cloud observations necessarily refer to cloudy weather and that pilot-balloon observations will refer chiefly to clear weather, and there is some evidence that there is a systematic difference between the two, but it does not seem to be large enough seriously to prejudice the results of using them as equivalent. The figures will be of great interest to any one who is endeavouring to elucidate the cause of the monsoons.

In Part viii. the relation of the monsoons to the general circulation of the atmosphere is dealt with, and the similarity of the north-east monsoon to the circulation over the North Atlantic is discussed. Dr. Harwood finds a very noticeable coincidence between the track of storms and depressions, as shown in the Climatological Atlas of India and in the Meteorological Atlas of the Indian Seas, and the monthly mean directions of the upper winds at the cirrus level. If this be more than a coincidence, and it seems to be so, it has an important bearing on the formation and propagation of cyclones, and shows that their source must be sought for in the upper winds rather than in the surface conditions.

The four Memoirs form a very valuable contribution, not to Indian meteorology only, but also to meteorology in general. W. H. DINES.

The Royal Photographic Society's Annual Exhibition.

THE Royal Photographic Society's Exhibition was opened on Monday, September 15, and will remain open until October 25, with free admission, at 35 Russell Square. The Scientific and Technical Section is probably the largest and in a general sense the most interesting that the Society has ever been able to arrange. Among the astronomical exhibits are photographs of nebulæ made at the Mount Wilson Observatory by the 60-inch and the 100-inch reflecting telescopes, illustrating Dr. Edwin Hubble's proposed general classification of nebulæ, and a frame that shows the different degrees of elongation of elliptical nebulæ. Dr. William J. S. Lockyer, director of the Norman Lockyer Observatory, Sidmouth, sends some striking photographs of star spectra, and what is, with little doubt, the most successful photograph of a meteor that has ever been secured. Various forms of clouds and their changes are illustrated by several contributors, and geological work by one exhibit from the National Geographic Society of Washington. Closely allied to this are several "survey and record" photographs from the United States and Canada, a very notable one being a photograph, by Dr. W. H. Wright of the Lick Observatory, of the Sierra Nevada Mountains in the neighbourhood of the Yosemite Valley, taken from the Observatory on Mount Hamilton. The details shown range in distance up to 135 miles, and several comparative details are indicated which clearly demonstrate the effect of the curvature of the earth in depressing the more distant as compared with the nearer hills.

Among the stereoscopic slides, the set of 50 by Mr. Herbert G. Ponting which illustrate China and Japan, and include the manners, customs, and occupations of the people, are specially notable. The new Section of Cinematography has twenty excellent exhibits by three authors. Press photography, commercial stage photography, lantern slides, colour photographs of many kinds, natural history photographs, radiographs (including the C.D.X. dental X-ray apparatus of Messrs. Watson and Sons, and a series of 18 dental radiographs), photographs transmitted by wireless, and so on, are all shown in their latest and most perfect forms.

Photomicrography in the service of technology and scientific investigation is exceptionally well illustrated. The Research Laboratory of the Eastman Kodak Co. shows the fibres, and their characteristics, that are contained in photographic paper pulp, and illustrate a new method of distinguishing rag and bleached wood pulp, presumably by differential staining and photographing through suitable colour screens. Mr. W. S. Gerecke, of the U.S. Rubber Co., has sent a long series that refer to

the manufacture of india-rubber and the changes that it is liable to. The British Photographic Research Association shows some of its latest results. Results obtained by the "Davon super-microscope," which has given rise to so much discussion of late, are illustrated by several photomicrographs by Mr. J. D. Jacobs, ranging in magnification from 1000 to 4000 diameters, each with a statement of the optical means employed.

Mr. P. P. Quayle, of the Bureau of Standards, Washington, shows a series of six photographs of the phenomena at the muzzle of a 0·45 calibre revolver when it is fired, taken by an apparatus that gives no evidence whatever of its presence in the pictures. A very interesting method of determining the effect of various conditions, such as stirring, changes of temperature, and so on, on reaction velocity by utilising the decay of luminescence in the Japanese ostracod, *Cypridina hilgendorfii*, is illustrated and explained by Dr. William R. Amberson. The "Mutochrome," invented by Mr. C. F. Smith, of Messrs. Adam Hilger, Ltd., is shown in action. By its means any pattern or design may be photographed and then projected full size upon a screen with the possibility of varying almost infinitely the colour and depth of tint of the various elements.

In concluding this necessarily incomplete account of the scientific part of the Exhibition, we wish to point out that in the prospectus this section is divided into eight well-defined sub-sections, each with its separate board of judges, and to ask, for the sake of students, that each of these divisions may be as clearly separated and indicated, in future, in the Exhibition itself. As it is, there is much confusion. According to the Catalogue, "Technical Applications" are scattered in eleven different places; some "Astronomical Photographs" are under this heading and some are under "Technical Applications," and so on. We would also add that it is very pleasing to see so rich a collection of work from the United States, and to be able to remark on the very high standard of excellence of all the exhibits.

University and Educational Intelligence.

LONDON.—H.R.H. Prince Arthur of Connaught has consented to undertake in November the formal opening of the Ramsay Laboratory of Chemical Engineering at University College, instituted in 1923 as part of the Memorial to the late Sir William Ramsay. A full course of study in chemical engineering will be provided in the laboratory in the coming session, leading to the degrees of M.Sc. or Ph.D. in chemical engineering. The course is designed to meet the demands of the manufacturing industries for men trained in the application of scientific methods to the design and operation of industrial chemical processes and plant. Special facilities are provided for research. Particulars can be obtained from the Secretary of the College.

SHEFFIELD.—The Council of the British Cast Iron Research Association has appointed Mr. J. G. A. Skerl to take charge of an investigation on moulding sands, to be carried out in the Refractories Department of the University and in the foundries of members of the Association. Mr. Skerl has for nearly three years been research assistant to Prof. P. G. H. Boswell, of the University of Liverpool.

APPLICATIONS are invited, from Egyptians only, for a whole-time lectureship in chemistry at the School of Medicine, Cairo. The applications, with particulars of qualifications, research work, etc., should be sent to reach the Director of the School before October 10.

A DEMONSTRATOR in metallography and pyrometry is required in the metallurgical department of the Royal School of Mines, Imperial College of Science ar Technology, South Kensington. Particulars of th duties of the post can be obtained from the secretar The latest date for applications is September 27.

APPLICATIONS are invited by the Harper Adam Agricultural College, Newport, Salop, for an Advisor Economist and an Advisory Chemist for servi in Shropshire, Staffordshire, and Warwickshir Candidates must hold a degree of a British universit and should have, if possible, some agricultur experience. Applications, with copies of three recer testimonials, must reach the principal of the Colleg not later than September 30.

DR. RUDOLF STEINER delivered a public lecture o education on August 30 in London, under the auspic of the Educational Union for the Realisation o Spiritual Values, the chair being taken by Mis Margaret Macmillan. He gave an exposition of h work as director of the Waldorf School at Stuttgar where his theories of education have been put to th test of experience, and announced that a school o similar lines will be opened at Streatham Hill, Londo next January. A principle which he holds to be o fundamental importance is the adjustment of edu cational methods and curricula to the biologica changes occurring in the pupil, and, above all, th changes that take place at the age of puberty. Th gives his doctrines a special interest at the preser time, when the question of "secondary education fo all" is being widely canvassed. It is perhaps misfortune that he has labelled them with the portent ous name "Anthroposophy."

PROSPECTUSES for the year 1924–25 have bee received from a number of technical colleges i London and the provinces. The Northampto Polytechnic Institute offers a great variety of course in mechanical and electrical engineering, optica engineering and applied optics, technical chemistry horology, and women's trades and domestic economy The part-time day classes for young persons employe in electrical and optical trades which have, owin to the propaganda work of a well-known electrica firm, been successfully maintained since 1918 despit the discouragement to which continuation classe have been subjected throughout Great Britain, wi be continued. The Sir John Cass Technical Institut provides evening classes for persons engaged i chemical, metallurgical, electrical, petroleum, and th fermentation industries, and in artistic crafts and th tailoring trade. Full facilities are offered in th Institute's laboratories for special investigations an research. The Cordwainers Technical College offer both day and evening classes in the technology o the leather-working industries. The former includ two-year courses in which the scientific an managerial as well as the more practical aspect of the industry are dealt with. A certain numbe of free places at the Imperial College of Science an Technology, South Kensington, are available fo students who desire to undertake post-graduatio study. The Technical College, Bradford, give particulars of three-year Diploma (Associateship courses in textile industries, chemistry, dyeing engineering, physics and, exceptionally, biology Entrants for these courses are required to pass College entrance examination of matriculatio standard if they have not already passed an examina tion of equivalent standard. The College offers als shorter courses, both full-time and part-time, an training in methods of research.

IN view of the efforts being made in Great Britain t foster interest in aviation, and of the announcement o Government support for light aeroplane clubs, specia interest attaches to the facilities available for the stud

...e science of aviation and of the art of flight. In ...dance with the opinion expressed by the Com... on Education and Research in Aeronautics ... "The Imperial College should become the Central ...ol for advanced study in Aeronautical Science," ...partment of Aeronautics was established in 1920–... that the Imperial College of Science and Technology, ...on, with the approval and financial support of ...e Government and under the direction of Sir ...ard Glazebrook. We have received a prospectus ...e reorganised department. It is now under the ...ction of Prof. L. Bairstow, who is Zaharoff ...ssor of aviation, and is assisted by two assistant ...ssors on design and on meteorology, and by ...ecturers on airships, on air navigation, on strength ...ructures, and on engine design. The assistant ...ssorship in meteorology is at present vacant: ...e other posts are filled by distinguished exponents ...eir subjects. As is to be expected, the depart...e: is in the main a school for post-graduate work, ...its aim is in the direction of the encouragement ...search, as well as in the co-ordinating of experi...al work carried out by individual workers at ...perimental stations in different parts of Great ...ain. A complete course takes two years, the first ...g spent in study at the College and the second ...search or in experimental work. A special one-... course is also offered for advanced students, ...terms at the College and the third term in experi...etal work at a research station or at the National ...sical Laboratory, Teddington. The Department ...eronautics at the Imperial College has already ...ieved considerable success: it will no doubt ...me one of the foremost centres of aeronautical ...y in the world.

TECHNICAL and evening classes provided by the ...don County Council opened this week. Last ...on about 120,000 students attended the evening ...stitutes in London and 51,000 the polytechnic and ...nical institutes, making all told about 170,000. ...s was an increase of nearly 7000 over the figures ...r the previous year. Increases in attendance ...urred mainly in the classes for women's subjects ...n for cultural and commercial education; there ... a slight decrease in the numbers attending ...nical classes. Forty years ago the number ...nding the "night" schools of the period was ...000. Despite the increase in numbers since then, ...e fact remains that, even to-day, only about one ...adoner in three continues his or her education ...ond the elementary school stage. Among recent ...elopments may be mentioned the teaching of ...roleum technology, oxy-acetylene welding, classes ...r the scale and weighing industry, and for textile ...ributors, musical instrument making, and an ...anced school of rubber technology, science teach...n in connexion with commodities and the marketing ...mmodities, technical optics, and aeronautics. The amount ...nt on vocational and cultural classes of this ...cription in London is about 1¼ million pounds a ...r. The bulk of this expenditure is met in equal ...portions by the Board of Education and the ...ndon County Council, the balance being derived ...m the fees of students and endowments. For the ...rmation of parents and older students, an ...strated "Guide to Continued Education in ...ndon" has just been published for the London ...unty Council by the University of London Press. ...is may be obtained from any bookseller at 6*d.* a ...py.

Early Science at the Royal Society.

September 21, 1664. Dr. Wren being desired to defer no longer the making of a larger telescopical moon for the Society, promised to do it against his next coming to London; upon which it was ordered that the treasurer should pay for a globe of that size, which Dr. Wren should choose at Mr. Moxon's. Several experiments were made. [Oldenburg, in a letter to Boyle, dated at London, September 22, 1664, gives some account of what passed at this meeting, where, he observes, they had the company of a Parisian academist, recommended to Sir Robert Moray and himself. I dare say (he says) he will extol our institution and proceedings to the sky, whensoever he comes; though I must say we grow more remiss and careless than I am willing to expatiate upon. Yet this I must say to a person, that I am sure hath a concern for our prosperity, that nothing is done with the king for us.]

September 22, 1679. Ordered—that Mr. Hunt take care to have all the instruments of the Society now in the custody of Mr. Flamstead at Greenwich immediately removed to Gresham College; and that Sir Christopher Wren and Mr. Hooke be desired to go thither, and take what care they can in it; and that in the meantime Mr. Hooke write to Mr. Moore about the same, and desire to have them carefully sent home.

September 23, 1663. The president gave an account of the experiment committed to his charge, about the descending of water purged from air, proposed formerly by Mons. Huygens, and several times tried before the Society; which the president affirmed to hold good upon every accurate trial. He was desired to prosecute the experiment with quicksilver, and to bring in the particulars of the whole success in writing, together with the solution of this phenomenon.—There was read a petition of the fishmongers, presented to the Parliament, concerning the annoyances, whereby the fry and brood of fish is destroyed, and the several ways whereby the same may be preserved. This was communicated by Mr. Graunt.—The operator was ordered to have ready against the next meeting the iron balls for the trying of gun-powder and gold-powder; as likewise the compressing engine; and the dog, for the cutting off a piece of his skin.

September 24, 1662. Mr. Winthrop read his paper concerning the conveniency of building of ships in some of the northern parts of America, there being several reasons, that may be propounded, as motives encouraging thereto. Among these, that it is not a new project the building of ships in those parts, for there hath been sufficient experience already made, there having been every year some built (great or small) for above these twenty years. There were this summer divers here at London, that were built over there, whereof two of about two hundred tuns: there is one now of an hundred tuns in this river, that was built there: there have been formerly some of three hundred and four hundred tuns built there. There hath been also, and is daily tar and pitch made; and much experience hath been made of the masts of those parts; many having been brought over hither.

1677. It was ordered that the officiating secretary taking short notes of all that passes at the Society or Council before the rising thereof, read the said notes in order to see that they be rightly taken.

September 25, 1661. Mr. Croune was desired to try some experiments of the weights of liquors: the lord viscount Brouncker to make the experiments of two pendulums: Dr. Goddard to prosecute his trials of sinking bodies under the surface of the water: Dr. Charlton to try the experiment of the freezing of salt water: Sir William Petty, a discourse on clothing.

Societies and Academies.

LONDON.

The Institute of Metals (Autumn Meeting), September 8.—W. M. **Corse** (autumn lecture): Recent developments in non-ferrous metallurgy in the United States, with special reference to nickel and aluminium-bronze. Some account is given of nickel, its occurrence, and smelting, and of the Orford, Mond, and Hybinette processes of refining. The copper aluminium alloy known as aluminium bronze is next described. This series of alloys has found many important uses, such as for worm gear wheels for motor trucks, automobile parts and other structural pieces requiring resistance to vibratory stresses or fatigues. The addition of lead to the standard aluminium bronze has given a new alloy of good wear-resisting properties. The dream of many a foundryman to avoid the use of sand for moulding purposes may come true, if the new Holley "long life mould" process using these moulds made of cast iron proves to be the success that is at present indicated. This applies to mass production work. There are also references to Ambrac metal, Frary metal, and the nickel chromium iron alloys.

PARIS.

Academy of Sciences, August 25.—M. Guillaume Bigourdan in the chair.—MM. **Bigourdan** and **Giacobini**: Observation of the total eclipse of the moon of August 14, 1924, made at the Observatory of Paris.—F. E. **Fournier**: Safety manœuvres, guarding against risks of collisions of two squadrons, in line of file, having to cross routes during fog.—Guiseppe **Belardinelli**: The resolution of algebraic equations.—Michel **Akimoff**: The approximate expression of Fourier-Bessel transcendentals of several variables, which occur in Kepler's problem.—P. **Appell**: Remarks on the preceding communication.—G. **Sagnac**: Classification of double stars.—T. **Batuecas**: Revision of the weight of the normal litre of methyl oxide. The value found, 2·1097, is in close agreement with that obtained by G. Baume in 1908 (2·1096). The atomic weight of carbon deduced from this is too high (12·033) and hence either the data for the compressibility of the gas require revision or the law of limiting densities of Daniel Berthelot is not rigorous for a gas so easily liquefied as methyl ether.—Léon **Moret** and Georges **Carrette**: Discovery of the marine Lutetian at the Roc de Chère (Lac d'Annecy).

SYDNEY.

Linnean Society of New South Wales, July 30.—Mr. R. H. Cambage, president, in the chair.—Marguerite **Henry**: (1) Notes on breeding Entomostraca from dried mud, and their habits in aquaria. The relative prevalence and persistency of the different species and their method of reproduction under artificial conditions are described. (2) Entomostraca collected in the vicinity of Auckland, N.Z. Of the ten species collected by Mr. T. Steel, one is new and is also the first of the genus Brunella to be recorded from New Zealand. Several of the species have hitherto only been recorded from the South Island.—J. R. **Malloch**: Notes on Australian Diptera. No. iii. Notes on some Diptera—Acalyptratæ, in which two genera (one in Chloropidæ and one in Agromyzidæ) and eleven species (five in Chloropidæ, two in Ephydridæ, three in Agromyzidæ and one in Asteiidæ) are described as new.—G. H. **Hardy**: A revision of the Australian Chiromyzini (Diptera). In 1920 the author published a paper revising the tribe Chiromyzini. The Australian species are here considered. The males of four species, hitherto only known from the female, are included, and another is described as a new species.

University Staffs and University Finance.

THE recent revision of the conditions of tenure and salary of the non-professorial staff at the University of Edinburgh, referred to in a letter published in NATURE of May 24, raises again the whole question of the position of these grades at universities generally, and the extent to which their position is satisfactory alike to themselves and to the institutions they serve. That such staffs believe themselves the victims of grievances is apparent to any one conversant with the present situation at most universities in Great Britain.

During the past quarter century, with the growth of specialisation and the increase in student numbers, a progressive change has occurred in the character of the work undertaken by a large proportion of these staffs. From the stage of being mere personal assistants to the professor, they are now very frequently directly responsible for honours courses and for the supervision of the work of research students. From the point of view both of disseminating existing knowledge and of opening up and exploring new fields of inquiry, they have become an indispensable section of every university.

Unless adequate facilities are provided, however, and the conditions such as to enable these individuals to devote their free time to original reading, thought, and inquiry, it is clear that this work cannot be conducted efficiently. It is notorious that demonstrators and lecturers of various grades, with increasing social responsibilities as they grow older, with no security of tenure, inadequate salaries for the positions they are expected to maintain or the interests they are required to develop, crowded in their grades with no prospect for the great mass of real advancement because of the paucity of higher posts, spend arduous nights away from home, teaching evening classes or undertaking other hack-work to supplement their meagre salaries. It is absurd to pretend that under such conditions their normal duties can be efficiently conducted, and an inquiry into the whole question of payment and the evils that are arising from continued under-payment is undoubtedly urgent before the rot has time to inflict permanent harm on university teaching.

The whole standard of staffing is affected by this question. The obvious lack of prospects of the junior staffs acts as a deterrent upon the better graduate from entry into the profession, and impels the ambitious demonstrator or lecturer, eminently suited as he may be to an academic career, to turn to secondary school teaching, where, with even inferior qualifications, he is certain to rise from 300*l.* or more per annum to 500*l.* or 600*l.* instead of remaining at a fixed salary

of 300*l.* or 400*l.* While it is true that certain individuals will always be attracted to university work, irrespective of the conditions, it is quite clear that the factor of low salaries is operating to drive the better type of graduate into school teaching and government service and to force the universities to retain on their staffs inferior men. The effect of this on our educational system will presently be apparent. While it is essential that the best personnel should be attracted to the academic teaching profession, they will only be induced to enter and remain by offering a career comparable to that obtainable in other fields. This can scarcely be said to be the case at present at Edinburgh, as we are informed in a memorandum issued by a committee of the staff that during the past year the average salary of the members of the non-professorial staff (248) was about 260*l.* and that for the professorial staff (52) about 1100*l.* It may be noted that where the work and responsibility of the one grade shade continuously into those of the other, this disparity in reward is too acute to be regarded as wholesome.

It is, however, not merely with the question of salary that these grades are apparently dissatisfied. While it is a fact that in a few universities, within the past few years, some members of the lectureship and readership grades have been admitted to membership of senates, no adequate scheme of direct representation of non-professorial grades on the senates and governing bodies of universities has been put universally into operation. There is in general no constituted machinery whereby members of these grades may make known their views on matters affecting the general policy of the university and their own interest. Such a state of affairs cannot, of course, endure. The devolution in administrative and educational responsibility and initiative, essential in the modern university, implies on the part of the staff a progressive experience and familiarity with problems affected by university policy which ought, in the interests of efficiency, to be fully utilised. No greater mistake could be made by any governing body than to regard the staff as mere employees or "hands."

Associated with these two aspects of the question, that of finance and that of policy, must be mentioned the tendency which has manifested itself of earmarking increases of capital, whether by gift or otherwise, for the foundation of new chairs or the creation of new buildings. If gifts of this nature are never to be expended on the salaries of the staff, not even towards the salaries of the additional staff required to carry on the work of the new extensions, the position of the non-professoriat must become more acute, especially since it has become customary to discuss the salaries of the latter always in relation to cur income.

From the point of view of the institutions th selves the problem is not easy. Faced with a decr in student membership and revenue from fees, incre in expenditure and decreases in grants, heavy r and requests for the extension of their functions, t lot indeed is not a happy one. The standard teaching must be maintained, the research spirit n be fostered, and the educational needs of a ri democracy catered for.

The problem is twofold—administrative and finan A little, perhaps very little, might be effected increased economies in administration, but in shaping of a progressive and enlightened policy ev thing is to be gained and nothing lost by the ful representation of the staffs on the governing bod On the financial side, however, the position is m more critical. The saturation point has proba already been reached as regards income from fe further increase is, moreover, undesirable in the li of present-day demands for the removal of finan barriers to a university education. Meanwhile, as immediate proposal, if the Government is in earn in its professions on education and on the injust of Local Rating, we see no reason why clauses empting educational institutions from local taxat should not be introduced into the Bill on Lo Rating which we understand it has in contemplati This would in effect secure to universities a contribut from local authorities equal to the present taxat paid by these institutions without the unpleas necessity of begging for such a grant. The suggest seems at any rate worthy of consideration.

In any event, the financial situation of the univ sities in Great Britain is really too critical for a mere tinkering to ease it permanently. All su institutions have more than a merely local inter and as such their finances require to be considered a broader basis. Their functions and responsibilit interweave and overlap, and to require each body produce a budget which balances in itself is fool finance. At what point the universities will be rea for drastic changes it is impossible to say, but so such change is inevitable and probably immine A broadening of the budgeting basis, a closer a more deliberate interlocking of the functions of separ institutions, would probably result not merely in more effective economy in administration, but wo unify the standard of grading in the staffs from university to another. The time is, indeed, ripe a Royal Commission on the financial position of Universities of Great Britain, excluding Oxford a Cambridge.

Rice.

By Prof. E. B. Copeland. Pp. xiv+352+18 plates. (London: Macmillan and Co., Ltd., 1924.) 21s. net.

If all the rice grown in India were planted in the British Isles, there would not be standing room for it. Yet the area under rice in India, with the exception of Bengal, is practically confined to a coastal fringe and is far from supplying the requirements of the people. The *per capita* ration for a rice-eating population would probably fall something short of three pounds a day, and the consumption in India is more than one pound. The staple food in a great tract in the north is wheat (there are 50,000 square miles of wheat in India), while the main cereal food of the population in the remainder consists of various millets. In other words, the ninety million acres under rice in India fall far short of the requirements of the country, and to a large proportion of the population rice is an almost unobtainable luxury. At the conclusion of the Armistice, festive gatherings were held in all parts of India, and at one in which the writer took part, representatives of all the neighbouring tribes were given a substantial meal. It transpired that some of these had never tasted rice, and, the quantity not being stinted, the unique spectacle was witnessed of the emaciated human frame swelling visibly during one short afternoon into comfortable rotundity.

China and Japan are two other great rice countries, and although statistics are not available, it is probable that somewhat similar conditions prevail there also, in spite of a distinctly higher scale of living, for we know that vast quantities of millets are grown in both of them. In northern China wheat is the main cereal. On comparing the maps of world distribution of rice and wheat, these crops are seen to be wonderfully complementary, the former spreading over the warmer portions and the latter over the colder; but the true rice zone has a much more restricted range, being concentrated in the monsoon tract in south-east Asia —Japan, China, India, Indo-China, and the Malay Archipelago.

Outside the region of the monsoons, rice appears sporadically all over the tropics, often being introduced to feed Asiatic labour, and even extends beyond the limits of the tropics into southern Europe, north and south Africa, and the New World (maize, of course, being the staple cereal there); but the area devoted to its cultivation in these parts is practically negligible when compared with that in the monsoon countries named above. The statement that one often meets with, that more than half the human race eat rice, is presumably based upon the large populations crowded into south-eastern Asia, but it should be accepted with some reservation. This appears to be recognised by Prof. Copeland, for he merely remarks that "it is probably the staple food of the greatest number of people."

The book is frankly one-sided, but this may, perhaps, be regarded as one of its greatest merits. Any attempt to cover the whole rice world, with its multitudinous varieties and agricultural practices, would require such a volume or series of volumes as would be a weariness to the general reader, if not out of his reach on account of costliness. We have nothing but praise for the author on the result of his effort, coupled with a sense of gratitude for his summarising, in small compass, the more important literature which has sprung up in various centres as the result of their invasion by western science. Most of this literature is altogether inaccessible, even to students in Great Britain. Prof. Copeland deliberately chooses the United States and the Philippines for his main descriptions of agricultural practice, on the sound plea of his thorough familiarity with the cultivation of rice in these countries. Of the countries dealt with, the United States claim fifty pages and the Philippines forty, while sixty pages are divided into short sections on India, Siam, China, Indo-China, Ceylon, Malaya, Java, Japan, Africa, Latin America, Spain, and Italy; more than half of these pages go to India (13), Java (8), Japan (7), and Italy (8). The rest of the book contains general chapters on botany, climate, soil and water, diseases and pests, seed and varieties, and the uses of rice; and in these chapters there are frequent references to such literature as has been published in all of these countries.

The choice of the United States and the Philippines for main treatment is abundantly justified by the fact that they represent the extremes in climate and agricultural practices. It has been stated that although labour is twenty times cheaper in China than in the United States, rice can be grown at less cost in the latter country. One man can only work one or two acres of rice in China, whereas, with the up-to-date agricultural machinery developed in cereal culture in temperate countries, a man can manage 80 acres in the United States. Yet the average yield of rice per acre appears to be only moderate. Analysing the crops in various countries given in the latest Statistical Year-book of the International Institute at Rome, we find that the greatest yields are obtained in Spain and Hawaii. High yields are also obtained in Italy, Egypt, and Japan; moderate in the United States, Java, India and Indo-China; while very low ones characterise Ceylon, the Philippines and Borneo. Judging from this point of view, the choice of the Philippines would not appear to be so satisfactory, especially as the total

output is very small in comparison with that of the great continental monsoon areas. But no country can be compared with these islands in the variety and picturesqueness of its paddy fields, as is at once evidenced by the two striking photographs of the Igorot cultivation in N. Luzon, fitly illustrating the labour involved through countless generations in terracing the almost impossible slopes among the mountains which are characteristic of the group. We must, however, guard against the idea that these terraces are in any way typical, and refer the reader to the pictures opposite to p. 234 for the more usual appearance of the paddy fields in the tropics. For the rest, the Philippines present sufficiently clear cases of the practices of indigenous tropical rice-growing; and there is always the author's plea as to his own intimate personal knowledge, which outweighs other considerations. His account of rice cultivation in the Philippines is indeed clear and interesting.

Prof. Copeland's agricultural classification of rices could, however, with advantage be somewhat widened, if for no other reason than to emphasise the extreme adaptability of this remarkable plant, on which the author insists. The classes given for the Philippines are four in number: clearing or *caingin*, upland or *secano*, *sabog* or broadcasting, and typical lowland (presumably transplanting). These are all present in India, although, as in the Philippines, the first named is extremely rare and fast disappearing; but at least two if not three classes should be added to make the classification more complete. The most interesting case is that of "dry paddy," which is grown just like many other crops in parts of India, on dry land with small rainfall under intensive dry farming methods. This paddy is drill-sown and best grown on black cotton soil; indeed, we believe that it is one of the curious *payira* crops, which will grow to maturity, once a sufficient fall of rain ensures satisfactory germination, without any further moisture than that of the air. This is obtained by the soil from certain moisture-laden winds ("crop winds," or *payira*), which blow during two or three months of the dry season. Then Indian "wet paddy" should be divided into two classes, which may be called swamp and irrigated respectively; the first, where the seed is sown on the margins of temporary lakes filled by the surplus of the monsoon rains and slowly drying up as the paddy ripens; and the second or ordinary lowland paddy, where it is absolutely necessary that a constant slow current of water four to six inches deep should pass over the ground, thus continuously changing the water. Then there is the "deep water paddy" mentioned by the author in another place: as to this, briefly, the writer has seen the oxen ploughing the land with the water almost hiding them completely, and the crop is said t frequently harvested in boats. It is, of course, obv that each of these methods will only be applicabl distinct varieties of the plant, and the agricult practices are entirely different. Some interes photographs of field work illustrate the chapter on Philippines, and these fairly represent those in monsoon tract.

In the United States section, Prof. Copeland centrates his attention on the irrigated, Californian z which is practically rainless during the growth of crop. The areas in thousands of acres in the principal rice States were in 1920 (the maximum) Louisiana 700, Texas 281, Arkansas 175, and Califo 162, but were considerably less in 1923. The b account given of the first three, the Gulf States useful, but, as good accounts in bulletin form available of the Californian area and much less regarding the other, we should naturally have p ferred a straightforward account of this larger older rice tract. This is especially so because of w we may call the fascinating account given by author of the section chosen, a term which can scarc be applied to such information as we have been a to gather on the Gulf States cultivation.

Turning to the general chapters, the first is appro ately devoted to the botany of the rice plant, and, we gather, this chapter is written at any rate larg by another author. The morphological details of rice plant are not very easy to describe withou series of adequate drawings, and this chapter is illustrated. There is no picture of the rice plant, of any of its parts, and some of the peculiarities, su as the leaf parts, are somewhat difficult to envisa while a clearly drawn longitudinal section of the gr would make much of this and later chapters m easy to read and understand. It is scarcely usual describe a graminaceous flower as "perfect," beca the rice plant has six stamens in place of the us three: the seed is described as "consisting of two t coats, the endosperm and the embryo," and t scarcely conveys the fact that it is built on identi lines with the wheat seed.

In the part dealing with the physiology of w paddy, a review of the literature regarding nitrog assimilation is quoted as showing that the rice pla differs from most others in depending on ammoniu salts rather than nitrates. These conclusions may correct for the free draining soils of Hawaii, but doubt whether they will be so for wet paddy the east. As bearing upon this subject, we m refer to work done by Harrison and others on t soil gases given off during the growth of wet pad in Madras, in a series of six memoirs during the peri

1-1920, which have apparently escaped the authors. Green manuring forms an important part in the local agriculture of the paddy fields, this substance being provided by the weed flora growing during the dry period, any vegetable residues in the soil, and often by large quantities of added matter in the form of special classes of leaves. Harrison, on investigating the result of puddling this vegetable matter, which is the orthodox method of preparing the land for paddy in the east, came across an extremely interesting case of symbiosis, between the rice plant and the surface scum. This scum consists of algæ and bacteria which form an impenetrable gelatinous film on the surface of the water as growth proceeds. The gases escaping from the decomposing green manure get entangled in the scum, and play a considerable part in the nutrition of the crop. On analysis, the bubbles are found to contain methane, carbonic dioxide, pure nitrogen, and free hydrogen, in quantities roughly indicated by the figures 70, 30, 5, and 3 respectively. But as the plants grow the bubbles change in constitution; the hydrogen and carbonic acid disappear and the nitrogen steadily increases in proportion to the methane, until at heading time and onwards it becomes the predominant constituent. The details of this change are too intricate to be dealt with here, but the net result is that the carbonic acid gas is utilised by the algæ for their growth with the usual evolution of oxygen which, unable to escape, highly oxygenates the water and thus enables the roots to live in apparently impossible anaerobic conditions. All of the nitrogen from the decaying vegetable matter is lost in the free state, and Harrison surmises that the nitrogen required by the plant is obtained entirely from the mineral salts stored as nitrate in the soil during the alternating dry period when the ground is covered by the weed flora.

Another much longer chapter, on "seeds and varieties," and mainly botanical, occurs later in the book, and as it considers numerous points dealt with in the first chapter it is a little difficult to understand its complete separation. This is one of the most interesting chapters in the book, and discusses in detail the many difficulties in the way of those who have made tentative attempts at classifying the rices of their locality. Varieties of rice differ morphologically and physiologically, and those which are difficult to distinguish in the first sense are not infrequently totally unable to live under the same conditions. One of the most marked distinguishing characters, perhaps, is the period required by the different rices to mature, a factor which fits in remarkably with the varying length of time during which, in a dry country like India, there is sufficient water available for the growth of the crop. The author dallies with the idea that this varying maturation of the crop may have something to do with the length of day or some similar factor of climate, but this is difficult to apply to India where, in the peninsula at any rate, there is little difference in this respect throughout the year, and there are probably more varieties of rice in India than in all the rest of the world together. A case quoted from memory will sufficiently explain the difficulty in accepting this explanation. In parts of the Tanjore delta, it is the custom to plant two kinds of rice together, a short and a long type (say, 4 months and 9 months). When the short crop is ready, the whole field is cut and the matured rice reaped; this drastic action is said not to injure the long paddy, still in the tillering stage, but even to improve its crop by causing additional branching of the hitherto shaded young plants.

After discussing the attempts of various authors at classifying the rices of their localities, the author presents, in the form of a carefully compiled *questionnaire*, a list of the information required in all future descriptions, covering two and a half pages of small print. Among other interesting details he refers to the uncanny faculty of rice-eating peoples of distinguishing the varieties in the form of rice bought in the market by their flavour and cooking qualities. This experience, gained in the Philippines, also astonished the writer in Madras, when an eminent Indian agriculturist informed him that he was able to distinguish 186 different local kinds by the same characters. Such statements have been received with suspicion in Great Britain and, naturally, would appear incredible to us, who are at best acquainted with only a few kinds, bereft by their preparation of their distinctive flavours and much of their nutritive qualities.

This, however, is not the only case met with of the extraordinary power of discrimination in food possessed by the great races of vegetarians in the tropics, and the writer has been accustomed to describe it as a separate sense which is unknown to the peoples of temperate regions and especially to meat eaters. To bring home the point in another way equally remarkable: in a recent severe drought, almost amounting to the official "famine," in South India, shiploads of Burma rice—practically the only kind which reaches Great Britain from the east—were brought over by the Government; and it is recorded that one of the greatest difficulties encountered by the officials in charge of the famine camps was to induce the starving people to eat this unaccustomed food. Some, possibly in a weak condition, were said to have died of starvation with an adequate quantity of this rice lying before them.

The most important part, however, of this long chapter of 64 pages is the summary prepared by Prof. Copeland of the scientific work, mostly done during the last decade, aiming at the improvement of the crop, both in the East and in Europe and the United States. The crops in the tropics are almost always grown as a mixture of varieties or even species, and it is obvious that the first step is always to separate these, whether by mass selection, which usually comes first, or by the separation of pure lines; and it is in the latter direction that practically all the economic successes have hitherto been obtained. This is the case with wheat, cotton, jute, and other crops, and more so still with rice: almost the only crop in which crossing has been the main line of work is the sugar-cane, which is always reproduced in cultivation by the vegetative method. But the analysis of the separate characters of these crops has also commenced in most cases, bringing with it a world of difficulties, which show that progress along this line in the improvement of crops will be a long and intricate matter.

In the case of rice, the author asserts that the raising of improved varieties by cross fertilisation is additionally handicapped by the form of the flowers. The glumes are so thick and tightly closed until just before or even after anthesis, that natural crossing is of the rarest; and he can only point to one case in which artificial pollination has been successfully accomplished. In this case, the severity of the method, cutting right across the glumes with a sharp pair of scissors and emasculating by fine forceps, seems sufficiently drastic to defeat the ends in view. We may only remark that various scientific workers in India do not appear to have met with this difficulty in crossing rice varieties.

Space limits prevent an adequate consideration of the remaining general chapters, namely, those on climate, etc., pests and diseases, and the uses of rice. The first of these is very short, but the questions that arise are referred to in all parts of the book. As regards the second, rice in the tropics has always been spoken of as a crop which, by its extensive method of cultivation, has escaped the devastation by pests and disease so largely met with in other crops, and this is largely true. Undoubtedly, for various reasons there has been less attention paid to the crop in the tropics than to other cultivated plants; but the formidable summary which is presented in the 50 pages devoted to the subject—largely of work in Europe and the United States—is sufficient to raise doubts as to the correctness of this comfortable preconceived idea. The absence of any picture, beyond a couple of plates by Dammerman of borers in Java, is a distinct loss in this chapter.

The uses of rice, dealt with in the short final cha of 10 pages, are briefly summarised; but, of cour great deal more could have been said about t The statement that the straw is "useless for fod will scarcely be accepted in India (as an example country where pasture is either non-existent or adequate), for paddy straw is the main and often only fodder during the greater part of the yea rice-growing tracts. It is true that this is less ma in Burma, where Indian visitors are accustome deplore the wasteful treatment of the straw; but owing to the sparse population, other sources available for fodder and there is a larger amoun waste land than in any part of India. This sp population is, it may be remarked, the chief re for the export of rice from the east, for padd scarcely ever grown as a "money crop," any n than millets are: it is only when there is a sur owing to an unusually good monsoon that enough be spared to send any to the countries of the w One last point, the use of the word "paddy" is ra strictly confined in the East to the crop and the unhusked product, and the additional meaning, w we have not met with before, of the space between bunds confining the water, is to be deprecated.

Science and Folly.

Foibles and Fallacies of Science: an Account of C brated Scientific Vagaries. By Prof. Daniel W. Her Pp. xiii+294. (New York: D. Van Nostrand 1924.) 2.50 dollars.

"LORD, what fools these mortals be," quotes reader as he lays down Prof. Hering's b "Foibles and Fallacies of Science." Astrology, transmutation of metals, perpetual motion, divinat prophecies, charlatanism, are some of the titles of chapters, and they give a good idea of the content a book which contains much curious and interest information.

But is the title of the book correct? The foibles fallacies about which Prof. Hering writes are certai not those "of science"; they are really those human nature." In fact, the chief interest of the b is the light it throws upon the folly of mankind, only of the so-called uneducated masses, but frequently of the highest intellects of the age.

All branches of science—at least all the older branc —have suffered from the pseudo-scientific and charlatan; in fact, one could judge of the extent which a branch of science comes into contact w human life by the extent of the foibles and falla which have grown about it. It is an instructive st

ry to work out the psychology of the makers of one of fallacy, and as the weather has always been a vorite subject for the pseudo-scientific, we may scully give a little thought to considering the ways of he weather prophets who figure so largely in Prof. Hering's book.

We need not devote much attention to the astrologer, or weather was not a speciality of his; it was only an ncidental. It is in the compilers of almanacs that we rs meet with the professional weather forecaster. Th first of these predicting almanacs appears to have be Old Moore's, which claims 1700 as the date of its irn and is, we believe, still going strong. Similar lmanacs are published in most countries, from which t would appear that there are still people who find hie weather forecasts interesting and probably useful. Tt it is not only unintelligent people who put their rit in such forecasts is clear from the remarks one has requently heard about the weather columns and iagrams which have appeared since the War in one of ur contemporaries devoted to country pursuits, travel n sport. How can we explain this except by that peiliar trait of the human mind which makes us remember those things which fit in with our preconceived ideas and ignore those which would prove us wng? Every success of a forecaster in whom we peeve is remembered, and as we take no particular ice of the failures, our impression—perfectly contentious—is one of unbroken or nearly unbroken uccess. Unfortunately, the same process produces an mpression of a series of failures on the part of the ficial forecaster, for no other reason than that, pecause we are British, we distrust everything official, ice his failures, and take his successes as a matter of ccrse.

What, however, are we to say about the makers of h forecasts? Surely they check their forecasts and nst be painfully aware of many dismal failures? Ay one who has had much to do with this class of wther prophet must have been struck by their great sincerity. There is no money to be made out of wther forecasting, so charlatanism is no solution of l problem. The explanation, and we speak from rch experience, is that these men have as a rule olved a most complicated system on which they base lir forecasts, and these systems are never in their al form. Hence, after every failure they re-examine e grounds on which they made their forecast, and n find that if they had only taken so and so into ount, or put less stress on something else, they would ve got a perfect forecast. The examination, instead making them mistrust their system, rather makes m realise how perfect it is if only it is accurately plied.

Prof. Hering also devotes several pages to rain-making and rain-makers, and describes the chief methods employed, but he does not mention the method, evolved as a result of the visit of the British Association to Australia, of electrifying the upper atmosphere by means of kites and balloons, which was offered to the Australian Government by a gentleman with a very appropriate name. Here again we meet with a remarkable amount of credulity; for in most cases the rain-maker thoroughly believes in his method and is sure it will work if only tried on a sufficiently large scale. There is, however, one clever man who makes a very good living out of rain-making. Mr. Hatfield is prepared to go anywhere and make rain on the principle of payment by results. If Mr. Hatfield makes no rain, he asks for no pay; while if he does make rain, he only asks for payment at the moderate rate of 3000 dollars an inch. His rain-making equipment consists of a huge tank 20 feet high, in which he brews a mystic chemical mixture which he says "opens up the clouds." Mr. Hatfield has been extensively employed on these terms in the United States, apparently to the mutual satisfaction of every one concerned. It is difficult to see anything wrong with this, viewed as a business transaction.

If we have estimated the character and motives of the pseudo-scientific weather prophet correctly, he is not such a bad fellow after all, and probably the same could be said of most of those responsible for the other foibles and fallacies described in the book, but we doubt whether Prof. Hering would agree with us, for he is somewhat hard on scientific folly. G. C. S.

Cambridge Biographies.

Alumni Cantabrigienses: a Biographical List of all known Students, Graduates, and Holders of Office at the University of Cambridge, from the Earliest Times to 1900. Compiled by Dr. John Venn and J. A. Venn. Part 1 (in 4 vols.). *From the Earliest Times to 1751.* Vol. 3: *Kaile—Ryves.* Pp. v + 504. (Cambridge: At the University Press, 1924.) 150*s.* net.

THE death of Dr. John Venn since the preface to Volume II. of this monumental work was written allows the reviewer to pay tribute to his magnificent services to Cambridge history and at the same time to emphasise the value of his son's contribution, not merely to the present volume, but also to the whole work. On him alone will now fall the duty of completing the Appendix, including the corrections and additions to the first three volumes. Isaac Newton apart, the present volume (Kaile—Ryves) does not include the names of many well known to science.

Among those whose names stand out on a first selection we may mention John Ray, the well-known naturalist, Nevil Maskelyne, Astronomer Royal, Thomas Millington, the alleged discoverer of sexuality in plants, and Robert Record, who introduced algebra to Britain. On slightly lower scientific grounds we may refer to Sir Hugh Platt, who conducted horticultural and agricultural experiments at Bethnal Green and in St. Martin's Lane, to John Lumley, who founded a lecture at the Royal College of Physicians, to Thomas Plume, founder of the Plumian professorship, to George Parker, second Earl of Macclesfield, president of the Royal Society, and to Roger Palmer, mathematician and political pamphleteer, afterwards created Earl Castlemaine and more generally remembered through his wife.

If science, however, does not figure prominently in this volume, the active part that Cambridge men played in all the religious and political movements of their time emerges clearly. Thus we find Thomas Legh, much employed in the suppression of the monasteries, and Matthew Mackarel, executed for supporting an insurrection against their suppression. Thomas Percye was one of the most active organisers of the Gunpowder Plot, while Thomas Knyvet searched the cellars of the houses of Parliament and discovered the plot. Several of the regicides were Cambridge men, as was also George Monck, Duke of Albemarle, largely instrumental in the Restoration. The ill-fated James, Duke of Monmouth, was Chancellor of the University, while Titus Oates tried two colleges but failed to secure a degree. Migration from one college to another was much more common in earlier times than nowadays.

Cambridge was also the home of many heretics. Hugh Latimer and Nicholas Ridley were the best known of those who were burnt at the stake. Many others settled in America and the West Indies to escape persecution. The strong position held by Cambridge men among English poets is reflected in the present volume in the names of John Milton, Christopher Marlowe, and Richard Lovelace, while other literary names worthy of mention are Thomas Nash, Thomas Otway, Matthew Prior, Andrew Marvell, and Samuel Pepys. The latter supplies one of the many human touches in a volume of short biographies. Others are found in the accounts of Thomas King, scholar of Eton and King's, who afterwards "kept the coffee-house in Covent Garden, called by his name"; of John Ruddle, the priest who exorcised a Cornish ghost; of Dr. William Oliver of "Bath Oliver" biscuit fame; and of Thomas Reresby, who was fined 1000*l.* in the Star Chamber for boxing the ears of Sir William Wentworth on the County Bench at Rotherham.

Our Bookshelf.

Uses of Waste Materials: the Collection of W Materials and their Uses for Human and Animal F in Fertilisers, and in Certain Industries, 1914–19 By Prof. Arturo Bruttini. (International Instit of Agriculture, Rome.) Pp. xx+367. (Lond P. S. King and Son, Ltd., 1923.) 12*s.* net.

One of the outstanding features of the War the abnormal shortage of food for man and be fertilisers for agricultural use, and of many ot substances regarded as essential for various econo purposes. The urgency of the need led to a dilig search for substitutes, many of which were found am unregarded bye-products and so-called waste mater and among wild and cultivated plants of every desc tion. Many of these substitutes merely supplied need of the moment, and fell into disuse as soon as crisis was past. Others were of more permanent va and in certain cases have retained a definite econo position.

As time goes on it becomes increasingly difficult realise the great amount of work and thought that applied to the discovery and exploitation of these wa materials, and Prof. Bruttini has rendered good ser to the community by placing on record not only det of the commodities themselves, but also a history of legislative and administrative measures adopted by various belligerent countries to deal with these matt No other writer has covered the ground so complet and the "Uses of Waste Materials" provides excellent outline of the information available to d with adequate references to more detailed papers wh such exist.

In outline the book deals first with the legislative administrative aspects, and secondly with the meth of handling waste materials and their various proper and uses. The subject is treated under the four m headings of human food, food for live stock, fertilis and alcohols, oils and other industrial produ though in some cases the same raw material be utilised for several purposes. Wherever possi analyses are given, and for feeding stuffs the appropri rations for different animals are frequently indicat As regards fertilisers, much experimental work has b carried out to test various residues, both as to th actual fertilising value and their relative value when cost of production is taken into account. Many h proved to be uneconomic on the latter score, but tests have indicated various sources of potential m ures, some of which may profitably be exploited. comprehensive table of contents and a number illustrations add their quota to the general usefulnes the volume under review, which should prove a valua work of reference to all agriculturists and to many those associated with industry. W. E. B

The Evolution of Mathematical Physics: Being Rouse Ball Lecture for 1924. By Dr. Horace La Pp. 48. (Cambridge: At the University Pr 1924.) 2*s.* net.

"The profound study of Nature is the most frui source of mathematical discoveries." In this quotat from Fourier, Prof. Lamb gives the keynote of lecture on mathematical physics. He traces the hist

of the subject during the nineteenth century, showing how work initiated on the Continent was brilliantly continued in Britain. The great time of Britain began with Green, who was followed by the Cambridge galaxy, whose enumeration of whom Lamb excludes men still alive and names only Stokes, Kelvin, Maxwell, Rayleigh. Then a time came when Britain went barren and it has remained barren ever since.

What is the cause of this barrenness? Is it that the well of genius has run dry, or is it that in some way Great Britain fails to provide the geniuses with appropriate opportunities? It is a century since Fourier stated the condition of mathematical progress, and in his lecture Prof. Lamb shows how the advances of the nineteenth century in Britain were due to the wide and deep knowledge of both mathematics and physics possessed by the workers. It is necessary to ask to what extent our universities are fulfilling the condition laid down by Fourier and now emphasised by Lamb? The answer is distressing. Not only are mathematics and physics divorced so that a man takes his degree in one or other and not in the two combined, but also the total range of mathematics is being found too great for a man to cover, and the tendency is to give a degree on an increasingly fractional knowledge of pure mathematics. If the present tendency persists, the time will come when each mathematician will have a minute knowledge of his own highly specialised branch and his angle of vision will be so limited as to make any advance impossible for him even in his own branch.

The total range of mathematics and physics as at present treated at Cambridge is too great for any man to cover in a degree course, as is also even the total range of pure mathematics as at present treated. So long as the present treatment of these subjects endures, we shall continue to sink in the slough of uselessness just described, and if the process of subdivision and specialisation is allowed to continue, our sinking will be the more rapid. The health of mathematics in Britain requires that Cambridge should discover a means to reverse this process and should in some way sufficiently condense the essentials of mathematics and physics to enable the individual to attain a real knowledge of both.

Gas Engineers' Compendium: a Collection of Statistics, Formulæ, Rules and Data for the Everyday Use of Gasworks' Officials and Students. Compiled by Experts. Pp. 292. (London: Ernest Benn, Ltd., 1924.) 32*s.* 6*d.* net.

A COMPENDIUM should at least be compendious, that is to say it should be comprehensive, complete, and compact; the information it contains should be accurate. This bulky volume fails to justify its title when tested by any of these criteria. General statistics and statutory requirements relating to the gas industry, gas-making coals, retort settings, purifiers, gas-holders, gas producers, by-products, flow of gases in pipes, and data relating to gas distribution generally, the mechanical characteristics of steel beams, etc. of various cross sections are amongst the subjects upon which information and useful particulars are given. We have failed to find tables referring to values of the elastic moduli of materials (and these are required in connexion with certain formulæ contained in the book), data referring to viscosities of gases, coefficients of expansion of substances, vapour pressures and numerous other physical data with which the gas engineer is intimately concerned. Room could be found for these if the thirteen blank pages, blank parts of pages, and wide marginal spaces characterising the volume were utilised; Kaye and Laby's Tables would serve as an example of the type and format of a volume much needed by the gas industry.

The incompleteness of information contained in the present volume is sufficiently illustrated by reference to the inadequacy of the statement on p. 272 relating to the melting point of firebricks—the value for "ordinary" firebricks alone is given. In like manner, one value only is given for the melting point of an electric lamp filament (unspecified). Inaccuracy of some of the information contained in the volume may be exemplified by reference to the tabulated melting points of magnesium, tantalum, and other substances given on the same page. Values of the specific heats of gases, etc. (p. 273), are given only at ordinary temperatures, and these in some cases are incorrect, and certainly in the cases of air and steam are not the generally accepted values. The mathematical section containing the elements of trigonometry, tables of squares, square roots, cubes, cube roots, logarithms, antilogarithms, and trigonometrical tables is possibly both the least and most useful part of the volume. The information contained in the useful part consisting of 16 pages of this section can be obtained elsewhere at a cost of one penny. This volume contains 292 pages (not all filled) and costs 32*s.* 6*d.* *Verb. sap.* J. S. G. T.

The Rock Tombs of Meir. By Dr. Aylward M. Blackman. Part 4: The Tomb-Chapel of Pepi'onkh the Middle Son of Sebkhotpe and Pekhernefert (D, No. 2). (Archæological Survey of Egypt, Memoir 25.) Pp. viii + 61 + 27 plates. (London: Egypt Exploration Society, 1924.) 42*s.*

THIS is a welcome continuation of Dr. Blackman's work, interrupted for nine years. Another large tomb, full of inscriptions, is here recorded, which had been opened by authorised native diggers, and left to destruction without adequate publication. These tombs of local princes give a detailed view of society some four thousand years ago. The great period of the pyramid builders was ageing to its fall, and pluralities and sinecures were the perquisite of high office. Forty-four titles belonged to the prince Pepionkh; some were the equivalent of modern degrees and honours which we express by initials, but others imply too much work for one man, such as Vizier, Chief Justice, Treasurer, Royal Deputy, Head of the Record Office, Keeper of the Granaries, and so forth. No doubt most of these duties were done by deputy, as he had sixty-four officials under him, all named in his tomb, and duly listed here. Beside these there are fifty relatives, who all had offices, and a hundred and ten dependants who also were thought worth mention. Thus more than two hundred persons all swelled the bureaucracy of this noble and lived on the estates. The good old man lived to a hundred, having "grown old very happily" and "never gone to bed vexed." The king under whom he thus flourished also lived to a hundred, in the peaceful

and fat autumn of that civilisation, soon to be scourged by a Syrian occupation.

The facsimile copies of all the sculptures and paintings are carefully executed, and are fully described; the inscriptions and translations have been discussed before publication, with various authorities. This may therefore be accepted as a final record, a kind of work which no nationality has done but our own, though sometimes executed for foreign patrons.

W. M. F. P.

Excavations in Malta. By M. A. Murray. Part 1. With a Chapter by G. Caton Thompson. Pp. iii+49+21 plates. (London: Bernard Quaritch, 1923.) 7*s.* 6*d.*

THIS record of excavations in Malta covers the work done by Miss Murray and her party in the years 1921–22. The most important site attacked was the cave of Ghar Dalam, in which Mr. G. Despott in the course of his excavation in 1916–17 discovered two teeth, since identified as belonging to Neanderthal man. An area of 40 feet by 60 feet was excavated down to rock, but beyond bones of the hippopotamus, some from a stratum which had hitherto proved sterile, no result of particularly noteworthy importance was obtained. Of the three remaining sites excavated, the most considerable was that of Borg en Nadur—remains on the slope of a spur running up from the bay of San Giorgio, at the top of which is the tower from which the site takes its name. The remains, which are well known to archæologists, include a dolmen flanked by an upright stone. In the area west of this dolmen, to which excavations were confined, a small apsidal building was brought to light which exhibits several points of interest and part of the wall of a forecourt. Miss Murray also examined the chamber behind the dolmen. No satisfactory evidence of stratification was obtained. The objects found included pillars, and pillar blocks, Bethel stones, hammer and polishing stones, a number of small chert implements and three fragments of bronze. The pottery, mostly fragmentary, Miss Murray, following Dr. Zammit, classifies as neolithic and bronze age, assigning a polished gray or black ware to the former, and the red with black decoration to the latter. It has been pointed out, however, that the attribution of the second type to the bronze age rests upon no very certain basis. If Miss Murray's results do not lead to any very decisive conclusions, she has produced a very careful, and therefore valuable, record of a considerable amount of work done in a limited time and at a trying season of the year.

Handbook to the Exhibition of Pure Science. [*British Empire Exhibition.*] Arranged by the Royal Society. Pp. 228. (London: A. and F. Denny, Ltd., 163a Strand, W.C.2, 1924.) 1*s.* net.

UNLIKE most Exhibition literature, which usually has a mercenary motive, patent or concealed, this publication is educational in the best sense of the word. The contributors to it are all investigators in the front rank, and their contributions summarise clearly and concisely all the recent advances in physical and biological science. Part I. contains articles concerning the structure of matter by "J. J.," Bragg, Rutherford, and Aston; relativity and astronomy are dealt with by Astronomer Royal and Eddington; "wireless" to by Glazebrook and Fleming; spectra by Fowl meteorology by Napier Shaw and others; origin of m by Smith Woodward; physiology by Starling, Har Hill, Cathcart; and this list is not exhaustive. Part comprises a descriptive catalogue of the exhibits in Exhibition of Pure Science at Wembley, together w introductory remarks by eminent specialists. In ev case it has been sought to trace the development o discovery or invention from the beginning to the lat application, and to show how the applications origina in research undertaken without any utilitarian moti The handbook will be greatly appreciated, not only those who visit the Exhibition, but also by all who interested in modern science; and those concer would do well to see it placed in the hands of all sen science pupils in the schools of the Empire.

An Essay concerning Human Understanding. By Jo Locke. Abridged and edited by A. S. Prin Pattison. Pp. xlviii+380. (Oxford: At the Clar don Press; London: Oxford University Pr 1924.) 8*s.* 6*d.* net.

IT is possible to appreciate the reason for this abrid edition of Locke's great Essay and at the same time regret its appearance. If it had to be done, no liv philosopher is so qualified to do it well as Prof. Prin Pattison. It is issued for academic reasons and appe to academic purposes. Every teacher of philoso knows that it is useless and undesirable to expect student to read the whole work intensively as he m read, say, Spinoza's "Ethics" or Kant's "Critique Pure Reason" if he would understand those phi sophers. Locke is prolix and also a large part of Essay has lost the interest and influence it had. On other hand, nothing is easier than to direct the stud as to what is important and what comparativ negligible. Abridgments are unwise. However w informed, it is certain, for it is human nature, that reader will suspect that something of importance escaped or been suppressed.

The Electrolytic Rectifier: for Electrical Engine Physicists, and Wireless Amateurs. By N. A. Bruyne. Pp. vii+75. (London: Sir Isaac Pitm and Sons, Ltd., 1924.) 3*s.* 6*d.* net.

THIS is a useful little book and will be helpful electrical engineers, physicists, and radio amateu The electrical engineer will appreciate the theory a the method described of using a rectifier to cha accumulators directly from alternating current sup mains. The book will also enable him to understa better the action of electrolytic lightning arresters. T physicist will find the author's experiments on the of neon lamps with rectifiers suggestive. His expe ments seem worth following up. The thousands radio amateurs who have learnt by experience that h cathode and mechanical rectifiers are fragile and cos to use for charging accumulators from the mains w learn that there are cheaper and no less efficient meth of charging them. The references given will be help to the serious student, and the description of the layer theory shows that it is in fair accord w experiment.

Letters to the Editor.

Five- (and Six)-Point Support: "Right as a Trivet."

THE earliest mention of the mathematical principle of Geometrical Fit, in five- and six-point contact, is found in the first edition, 1867, of Thomson and Tait's "Natural Philosophy," p. 131, § 198: "As an additional degree of freedom is lost by each successive limitation of a point in the body to a smooth surface, so such conditions determine completely the position of the body.

"Thus if six points properly chosen on the barrel and stock of a rifle be made to rest on six convex portions of the surface of a fixed rigid body, the rifle may be replaced any number of times in precisely the same position, for the purpose of testing its accuracy."

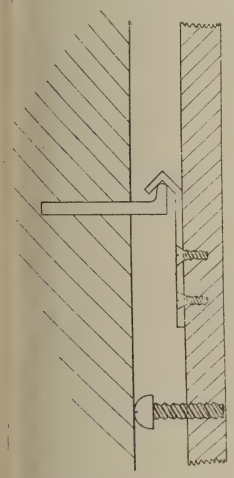

FIG. 1.—Five-point support for pictures on a wall.

This message has not yet received the attention it deserves in the design of mechanical apparatus, for example, the Six-Point Rifle Rest. It is ideal in repetition work such as rifle small arm manufacture, where the parts require to be assembled at random. In Geometrical Fit there is no need for machining of the parts; the fitter's occupation is gone; and "Right as a Trivet" is an exact proverbial description of a perfect mechanical theorem embodying the Axioms of Geometrical Fit.

In the five-point support we proceed to describe, one contact is suppressed, allowing the body one degree of freedom, as we see in the trivet on the bars of a grate, free for a sidelong displacement, but always coming to a steady bearing. The sixth point is encountered by sliding the body on against a stop.

A length of electric conduit tube round a room will serve in the same way for the support of pictures, the tube resting in brackets fastened to the wall at dado height. Hooks on the back of the frame will hold the picture up at an appropriate height, leaving it free to be displaced sideways to any desired position; the cant from the vertical is settled by a round-headed screw in the back lower bar of the frame. The same method can be applied to bracketing out a piece of apparatus from the wall, leaving it free to be lifted off and replaced, and yet quite firm and steady in position.

The wall of a modern laboratory, for appearance and cleanliness, should be not the rough brick surface as at the Cavendish Laboratory, but of glazed brick with a dado some way up from the floor; a mop passed over it will wipe off the dust. A nail cannot be driven into this surface; and so the architect should give instructions for an iron plate to be built into a course of the bricks, at an appropriate level of dado, with a cornice lip projecting slightly; and no more is required for the support of apparatus or blackboard, wherever desired, or however heavy, as in Fig. 1.

If a nail must be driven, a board should be kept for the purpose, and then the board is hung up where required as a blank blackboard.

The method is ideal for a picture gallery, a Royal Academy exhibition. The Academician will stake out his claim and settle the height of his picture, and of the hooks in the back of the frame; and if dissatisfied there is no difficulty in his removal to another site on the wall.

In the oldest Academy of Art, the Pinacotheka on the Acropolis of Athens, the walls are still smooth marble, with no sign of a nail driven, and the professor, our guide, was puzzled how the pictures were hung, until I directed his attention to the groove in a horizontal course, giving the support described above.

Applied to the ballistic pendulum (Fig. 2) the five-point principle requires a suspension of five wires in appropriate spacing, to allow a block or sleeper to recoil parallel to itself; and no consideration is required of centre of percussion or oscillation; the point of impact is practically immaterial. The block moves all together, as in Euclid's definition of a solid body.

The suspension is made from a bracket held up

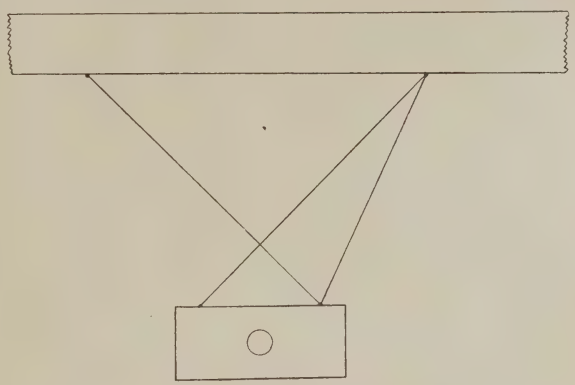

FIG. 2.—Ballistic pendulum.

against the wall in the manner described above; not from the roof, for which the architect never makes provision, and inaccessible at that, especially in a fire with the roof full of smoke. The electric chronograph has replaced the ballistic pendulum for careful velocity measurement, but there are still many applications where the pendulum can prove useful, economical, and accurate.

The psychology of the recruit must be considered at the first introduction to the use of his rifle, so as not to waste confidence in himself by throwing away his first shots. Ordered to lie down on the ground behind a rifle rest designed on this six-point principle, with the rifle in it trained on the target, say at 500 yards, he will be directed what to see on looking through the sights, and instructed in simple snapping practice under the careful eye of his instructor to see there is no flinch or wink on pulling the trigger, going through all the preliminary motions of opening the breech and inserting a cartridge, and ejecting the empty cartridge case by working the bolt. A live cartridge is then inserted without notice, and on pulling the trigger the unsuspecting recruit feels the kick, how it is not formidable with a proper hold. After this he can continue with his allowance of drill rounds, and find all shots in the bull's-eye. He will have acquired confidence in his weapon and himself, and realise that he can continue this standard of marksmanship; if only he holds the rifle straight and himself steady, the weapon and ammunition will do the rest. He is not discouraged at the outset by the

depressing experience of finding all his first series of shots going he knows not where.

In Geometrical Fit there is no need for machining the parts. The parts of a rifle can be stamped out in drop forging, and assembled at random, the natural skin left untouched to avoid rust. The only surface to require machining is a sliding contact, as of the bore of the rifle for the passage of the bullet, and the bolt action of the breech mechanism. When a rifle is assembled and tested by the proof rounds, the opportunity can be utilised of adjusting the sighting at the same time. The rifle is placed in the six-point rest, and the proof rounds fired, without aiming, at a card in the line of fire. The centre of mean impact is then marked on the card, and another workman follows to place the foresight in line on the muzzle, to be brazed on there afterwards. The operation of proving and sighting is thus carried on simultaneously from the same six-point rest.

These principles were too simple to appeal to the Enfield tradition; the complication of the bolt action was adduced as a triumphant refutation when I attempted to explain the theory.

Lord Kelvin had occasion to complain of the dogged opposition of his workmen, and was compelled to put it to them as a personal favour to carry out the six-point idea in his apparatus, allowing them the liberty of classing him as a fool, and paying their wages all the same. At Woolwich I was once just in time to recommend the principle for the suspension of a series of coat and hat racks, requiring to be removable and replaced on occasion. But we did not reckon with the smartness of the sapper artificer, careful to make a mechanical fit sideways, obliterating that degree of freedom.

The use of these brackets was made conditional on the possibility of their removal at a moment's notice. But, as a consequence of the R.E. science, the brackets could not be replaced without an intolerable amount of trial and error, calculable on the algebraical principle of Permutations.

At Finsbury Technical College the advice of Prof. James Thomson was enlisted by Perry for the design of a blackboard, in accordance with his idea of the requirements, and the following description is quoted from "Technical School and College Building," p. 152, by E. C. Robins, 1887.

Prof. James Thomson's blackboard, shown in plate 5 there, is so sensitive to movement, it may be moved up and down with the little finger, although the blackboard itself measures 14 feet wide by 6 feet 6 inches high.

According to Prof. Perry, "It is absolutely necessary the lecturer should not rub out a mathematical formula until the end of the lesson, and this requires a very long blackboard, the longer the better. As one who has to teach mathematics I say a blackboard should not be less than 30 feet long. A long blackboard is usually fixed to the wall. You can write perhaps at 6 feet from the ground to 3 feet, but it saves much needless moving to be able to write all formulas at about 5 feet from the ground.

"It is of importance then to move the whole of the blackboard up and down with a touch of the finger, as Prof. James Thomson's arrangement enables you to do.

"Instead of hanging the blackboard by two chains over four pulleys, and having a very heavy balanced weight for the whole board, involving a tremendous amount of friction, we hang the ends of a well-framed board by two chains from the long arms of two levers; the shorter arms carry a heavy balance weight, and the only place where friction can occur is at the fulcrum of the levers.

"This allows a very large motion of the board for small motion of the balance weight, a great convenience. When these fulcrums are well oiled, a touch of the chalk at any point of the board is sufficient to lift the blackboard."

Vertical grooves give sliding contact, arranged on scientific principles, to render jamming impossible, by the use of only three contacts. But Perry here had the same experience and difficulty as Thomson with the workmen. He complained how after he had been transferred to Kensington, he returned to find the blackboard had been put right by a skilled workman, quite sure the number of supports was insufficient, adding a fourth sliding contact. The result of making what he called a workman-like job was for the blackboard to jam.

However, in a recent visit to Finsbury Technical College, I found the blackboard had been restored again to its original Thomson design, and was in proper working order, easy up and down.

G. GREENHILL.

Mendelism and Evolution.

MEMBERS of the British Association during the recent Toronto meeting have had put before them the available evidence concerning the so-called "White Indians" of Panama. The purely biological interest of the discovery turns out to be as great as the anthropological; and, since it bears on correspondence which has recently appeared in the columns of NATURE, I should like to comment briefly upon it.

In the first place, then, it appears clearly established that the "white" condition behaves as a simple Mendelian recessive. The normal dark colour is completely dominant; there are no intermediates; all the "whites" show essentially the same deviation from normal; white × white gives only whites, but whites may be produced (together with normals) from the mating of two persons phenotypically normal.

The condition has been described as "partial albinism." If by this is meant simply any condition in which normal pigmentation is reduced, the term is applicable; but it should be noted that these people possess yellow hair and hazel eyes.

All the authorities who have examined them are agreed that the condition has no racial significance; the racial type has not been altered save in the one respect of pigmentation, nor can the condition possibly be interpreted as resulting from previous crosses with Europeans. In any case, the discovery that the condition depends on a single-gene Mendelian difference from the normal implies both these results.

Now, however, for the biological and evolutionary significance. Not only are these "mutants" (as they clearly appear to be) perfectly capable of healthy existence and reproduction, but they are coming to form a community of their own. The normally-coloured members of the tribe have a feeling against marrying "whites," with the result that the mutants mate almost wholly with others like themselves, and thus in course of time have formed a nearly closed, self-reproducing community of several hundred souls.

Mutation: consequent preferential mating: consequent establishment of a definite intra-specific unit: with the future consequence that any further mutation occurring within this unit will remain confined to it, and the difference between mutated and type stock thus become accentuated. Here, in man himself, is a case showing with almost diagrammatic clarity how evolutionary change may originate in single mutations of considerable magnitude. JULIAN S. HUXLEY.

The Marine Biological Laboratory,
Woods Hole, Mass., U.S.A.

Agricultural Research.

THE address delivered by Sir John Russell, as president of Section M (Agriculture), at the recent meeting of the British Association at Toronto, may be characterised as a somewhat despondent survey of present day activities in agricultural research, with particular reference to those branches of the subject allotted to the Rothamsted Station and the special problems upon which the workers there have been engaged. It may be worth while to give consideration to some of the more general aspects of applied research to which Sir John Russell's remarks inevitably direct attention.

When philosophers, as they then called themselves, first turned their attention to the problems presented by the life of the plant, they were not long in finding that the pioneer science of chemistry enabled them to throw an immediate light on what we may now regard as the crude fact, that plant life is dependent for food upon an adequate supply of certain elements, such as carbon, nitrogen, phosphorus, and potassium. It was an easy step to supply some of these elements by "artificial" means. The result was that, dating from the forties of the last century, the practice of applying "artificial" manures received an immense impetus: so much so that farming practice was almost revolutionised. It became possible not only to raise the level of food production from a given area of land, but also to maintain that level indefinitely.

The material consequences of these early discoveries were so great that they created a belief in the efficiency of scientific research as applied to husbandry which has been held to justify the expenditure by the State, as well as by other agencies, of larger sums than have hitherto been devoted to research of any other description. But during the last eighty years science has presented only one other gift of an economic importance equal to that just indicated. Mendel and his belated disciples have taught us to regard the plant as a plastic organisation which can be systematically moulded in desired directions. Sir John Russell has catalogued the remarkable results of the work of Biffen and others.

Yet it cannot be denied that the agricultural sciences have made great advances in other directions in these long years. Our knowledge of the factors concerned in the growth of animals and plants is almost inconceivably greater than it was eighty years ago. Why is it then, that, as judged by economic tests, farming practice has been so little modified that even Virgil's "Georgics" may still be read as a textbook? One reason may be suggested. The growth of a plant or animal is affected by a number of environmental causes beyond human control. A severe hailstorm, a rainy season, may render nugatory all the efforts of the most skilful and scientific husbandman. He earns his living really by virtue of the law of averages. If old tradition is right, he rings a cycle of changes in a lunar period of nineteen years. It is a fair inference, therefore, that he is not likely to be much moved by scientific evidence that a certain course of action will produce a better result *of the order of difference* that he associates with a normal seasonal variation. If, for example, the supposition is made that the yield of any crop on a particular field will vary normally by 10 per cent. from year to year, a scientific improvement, which, if adopted, increases yield by 10 per cent. in any one year, is scarcely likely to interest the husbandman. It may be, therefore, that science has failed to produce discoveries of sufficient magnitude. "Artificial" manuring, it is true, may be said to have been a discovery of the order of 100 per cent.; and the science of plant-breeding may be said to have involved differences of the same order.

In Sir John Russell's address, consequently, one detects a feeling of disappointment. We have passed through, he says, a "pioneer period with . . . the disadvantages of certain lack of perspective, failure to follow up important issues, and some narrowness of outlook." He suggests that steps should be taken to secure the co-operation of a team of workers in every science bearing on agriculture—the members to be drawn from all parts of the British Empire. The proposal is scarcely in the region of practical politics. After all, the epoch-making discoveries of science have not come from team work—nor from what is sometimes termed "directed" research.

The Member of Parliament and the Treasury official are apt to think of research as if it functioned like a penny-in-the-slot machine—a mechanism which unfailingly gives "results" for the inserted coin. Such and such an industry should form a Research Association, accept a grant, and forthwith grind out results good for the industry concerned. The whole history of scientific effort, however, is a record of individual successes in so-called "pure" science, and, with due respect to the Director of Rothamsted, what appears to be wrong with agricultural science is that it is too agricultural. If, as he says, the "co-operation of a plant physiologist" is needed, let us take care that the worker is not tied to the study of agricultural plants, and if, in consequence, he is a worker in "pure" botany, let us see that he gets as liberal a grant as his brother working in agricultural botany. At the present juncture, research in pure botany is languishing in all our universities, and yet, on Sir John Russell's admission, the advances made by one branch of the science, that of plant-breeding, have far outdistanced any discoveries in the sciences with which he is directly concerned.

The lesson one may venture to extract from the address of the Director of Rothamsted is that it is high time that the State turned its attention to the need for fostering scientific research in pure science. Directed research, that is, research directed to secure definite economic results, is in danger of becoming outworn for lack of draughts from the *pocula sacra* which University research in pure knowledge exists to provide!

CANTAB.

The Vibrations of Air in Organ-Pipes of Unusual Shapes.

IN an interesting letter published in NATURE for August 30, Principal J. A. Aldis discusses the vibrations of air in organ-pipes of unusual shapes, and gives a number of elegant formulæ for calculating the frequencies of the tones in certain cases. The date of the investigations (1867–1868) gives them a special interest, since they were carried out some three or four years before the publication of Rayleigh's well-known paper on "The Theory of Resonance," in which, by the introduction of a quantity which he called the "conductivity" of an orifice, he was enabled to give a simplified treatment of the theory of bottle-resonators and of pipes with restricted mouths.

I was at first somewhat surprised to see that the formula given by Principal Aldis for the frequencies of the tones of bottle-pipes agreed satisfactorily with observations, apparently without any restriction as to the size of the bottle. The formula is obtained by assuming the existence of stationary plane waves in the two parts of the bottle—*i.e.* in the neck (or mouth part) and in the stopped part—and the continuity of the pressures and velocities at the

junction of the two parts. The formula is

$$\tan mh \,.\, \tan mk = \frac{\text{area of mouth part}}{\text{area of stopped part}}, \quad . \quad (1)$$

where h is the length of the mouth part, k is the length of the stopped part, and m is $2\pi/\lambda$ or $2\pi n/a$ (n = frequency, a = velocity of sound). While this formula might be expected to be satisfactory in the case of bottle-pipes with parts of moderate length, it would, I think, scarcely be expected to hold good if the length of the bottle were much less than a quarter of the wave-length belonging to the fundamental tone of the bottle. In such a case we should expect to get better results by using Rayleigh's formula for the frequency of a Helmholtz resonator, namely—

$$n = \frac{a}{2\pi}\sqrt{\frac{c}{Q}}, \quad . \quad . \quad . \quad . \quad (2)$$

in which, for a bottle-pipe, c would be the hydrodynamical conductance (Rayleigh's "conductivity") of the mouth part and Q the volume of the stopped part. It appears from this, therefore, that for small bottle-pipes the important factor is the *volume* rather than the *length* of the stopped part.

The point to which I wish to direct attention, however, is that, notwithstanding the apparent diversity of equations (1) and (2), Rayleigh's equation (2) can be obtained as a limiting form of (1) when h and k are made small compared with the wave-length. In this case we have approximately $\tan mh = mh$ and $\tan mk = mk$, and if σ_1 is the area of the mouth part, and σ_2 the area of the stopped part, we obtain

$$m^2hk = \frac{\sigma_1}{\sigma_2},$$

or

$$n^2 = \left(\frac{a}{2\pi}\right)^2 \cdot \left(\frac{\sigma_1}{h}\right) \Big/ \sigma_2 k.$$

Since σ_1/h (area divided by length) is the conductance of the mouth part (end-correction being neglected) and $\sigma_2 k$ is the volume of the stopped part, we have

$$n = \frac{a}{2\pi}\sqrt{\left(\frac{\sigma_1}{h}\right)\Big/\sigma_2 k} = \frac{a}{2\pi}\sqrt{\frac{c}{Q}}. \quad . \quad . \quad (3)$$

It appears, therefore, that either of the two forms (1) or (2) may be used for obtaining the approximate frequency of the fundamental tone of a small bottle-pipe. Rayleigh's formula, however, has the disadvantage that it does not help us to discover the frequencies of the overtones.

If in equation (1) we suppose h, but not k, to be small compared with the wave-length, we have the case of a pipe with a narrow mouth. Equation (1) becomes

$$mh \tan mk = \frac{\sigma_1}{\sigma_2},$$

or if $\sigma_1/h = c$ (the conductance of the mouth),

$$\tan mk = \frac{c}{m\sigma_2}, \quad . \quad . \quad . \quad . \quad (4)$$

an equation which was given by Rayleigh in 1871 ("Scientific Papers," vol. i, p. 46, equation (15); the right-hand side is inadvertently shown with a minus sign).

Again, if k but not h is small compared with the wave-length, we have the case of a long tube connected with a reservoir. Equation (1) becomes

$$\tan mh = \frac{\sigma_1}{m\sigma_2 k} = \frac{\sigma_1}{mQ}, \quad . \quad . \quad . \quad (5)$$

Q being the volume of the reservoir. This equation was also given by Rayleigh.

Abney Sectors in Photometry.

THE following may be of value to those interested in photometry.

The instrument known as the "Abney Sector" used for reducing, for photometric purposes, the intensity of powerful illuminants, such as searchlight projector arcs, by means of a rotating disc fitted with continuously variable sectors, is difficult to construct, and, unless perfectly made, is liable to stick at high speeds.

I have found the following a simple and efficient instrument.

A disc 12 to 18 inches in diameter, in which curved edged V-shaped slots are cut (Fig. 1), is mounted vertically on a board together with a driving motor. Between the illuminant and the disc, close to the latter, but mounted separately, is a screen in which is cut a small rectangular aperture. The beam of

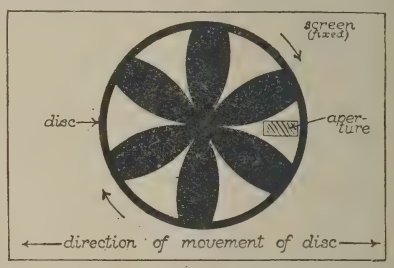

FIG. 1.

light under investigation passes from the source through the aperture and interruptedly through the rotating sectors of the disc to the photometer. The rays are alternately obstructed and allowed to pass by the sectors of the rotating disc, just as in the case of the Abney Sectors. By moving the board on which both disc and driving motor are fixed with respect to the aperture, more or less obscuration as desired may be obtained.

The board may move in a groove graduated to show degrees of obscuration.

Aurora, Potential Gradient and Magnetic Disturbance.

IN view of suggestions which have been made from time to time that a relationship may exist between the intensity of the earth's electric field and the phenomena of the aurora, or of terrestrial magnetism, the available data from Cape Evans—the winter quarters of Capt. Scott's last expedition—have been examined. The original intention to make a comparison between the auroral data and the potential gradient data was formed on the publication of the first meteorological volume. This intention was stimulated by the fact that the time of maximum of the daily variation in potential gradient at that station lay between the time of maximum frequency for auroræ (4 A.M.) and the time of maximum magnetic disturbance (10 A.M.)—in time of the 180th meridian. In addition, Dr. Simpson has recorded slight anomalies in temperature and in pressure at the time of day when the aurora was most frequently observed. By the courtesy of Dr. Simpson, copies of the original data for potential gradient were made available, but it was found that the hours during which conditions were favourable both for observations of aurora and for potential gradient measurement (wind less than 10 miles per hour) were not sufficiently numerous to repay investigation.

On the other hand, it is known that the activity of e aurora is related to magnetic disturbance, and ta exhibiting this relationship have been published reports of the Expedition ("Terrestrial Magnetism" d "Observations on the Aurora"). In these rcumstances, Dr. Chree kindly lent his original ures for hourly character number (representing agnetic disturbance), and these were used for making comparison with the figures for potential gradient ring winds up to 5 miles per hour, for the period arch 1911 to February 1912.

For the purpose of this comparison, the potential adients corresponding to Dr. Chree's magnetic aracter numbers (0 = slight and 2 = great magnetic isturbance) have been meaned for all hours during nich the wind was not greater than 5 m.p.h. Generally eaking, the mean gradients corresponding to these aracter numbers vary during the course of the day nilarly to the curves shown on p. 315 of Meteorology," vol. i. The mean value for the ar corresponding to

Character number 0 is 89 volts/metre.
,, ,, 1 is 90 ,,
,, ,, 2 is 96 ,,

aking, however, means for each hour of the day, id allowing equal weight to each hour, the corre-onding numbers are 88, 89, and 91. The evidence ems, therefore, to be against any direct connexion etween magnetic disturbance and potential gradient this station.

Figures have been derived for the mean value of e potential gradient at each hour of the day, for ur periods of three months each, and these figures so do not encourage much hope in the reality of ch a connexion. The mean values for the four arters (commencing for convenience in February, id equal weight being allowed to the mean value for ch hour of the day) are :—

Quarter.	Magnetic Character Number.					
	0		1	2		
Feb. to Apr.	82 (82)*	volts/metre	81 (83)*	88 (88)*	volts/metre	
May to July	77 (76)	,,	77 (78)	78 (78)	,,	
Aug. to Oct.	93 (93)	,,	93 (94)	93 (96)	,,	
Nov. to Jan.	106 (111)	,,	98 (99)	107 (107)	,,	

* The figures in brackets represent the corresponding means when each servation during the quarter is given equal weight.

A Substitute for the McLeod Gauge.

THE letter in NATURE of August 23, p. 276, fails justify an attack on the McLeod gauge. The eory that water is absorbed by glass is a theory ly, of which there is no proof, and there is no proof at the McLeod gauge reads incorrectly or even at it is inconsistent. Any variation can be observed ly by comparison with another method of measur-g low pressure, which is just as likely to vary or be consistent as the McLeod gauge. Animal emana-on, the glass-blower's breath for example, is very ifficult to dislodge from the surface of glass and ight easily cause a disturbance in the electric spark henomena.

A final pressure of 0·001 mm. is mentioned; this eans a pressure which will support a column of *ercury* 0·001 mm. high. The McLeod gauge is the nly practical means of determining this measurement irectly.

In a former letter we were told that the McLeod gauge may have special uses (such as the calibration of other gauges) "under rigidly controlled conditions." This can only mean clean glass, pure mercury, and an efficient drying medium, but it goes to prove my assertion that "there is no substitute for the McLeod gauge, in its perfect measurement of low pressures, expressed in height of mercury column."

HENRY A. FLEUSS.

47 Albert Road,
Caversham, Reading,
September 4.

MR. FLEUSS's letter answers itself. But may we trespass on your space for the last time in order to correct a misunderstanding which others than Mr. Fleuss have shared, and for which our original letter was doubtless responsible?

We never intended to deny that the McLeod gauge, used rightly, is a thoroughly trustworthy instrument and almost indispensable for the calibration of all other gauges, except possibly the Knudsen. But we deny that, as it is often used, it is trustworthy or convenient. It is still, or was recently, an almost universal practice to attach a McLeod to every pumping system and to take readings on it a few minutes after the apparatus has been exposed to the air, and long before the condensed water is removed from the glass. McLeod gauges used in such circumstances are, we repeat, "cumbrous and misleading devices," "mere relics of the past." They are responsible for the ridiculous underestimating of pressures which is still common in the papers of serious investigators. It is for gauges used in such circumstances that we advocate the Pirani gauge as a substitute. Its increasing use shows that we are not alone in our opinion.

J. W. RYDE.

Chimæras Dire: Transplantation of Heads of Insects.

I AM sorry that Prof. Przibram (NATURE, September 6, p. 347) should think that I treated Dr. Finkler's statements with unbecoming levity. The object of my letter was simply to direct attention to Dr. Blunck and Dr. Speyer's criticisms of Dr. Finkler's work and not to express agreement with one side or the other. Now that Prof. Przibram has undertaken to reply to these criticisms, the accuracy of my brief summary is perhaps no longer a matter of great importance, although I fail to see that it is in any way seriously misleading. It is true that I ought to have written "thorax" instead of "wing-cases," and also that Dr. Finkler has not yet told us with what he fed his inter-specific monsters; but I still think that the sentence "a male head led a female body into unwonted perversities" is not an unfair version of what Dr. Finkler has said. To those of us who have only a scanty knowledge of the subject it seems a less extraordinary thing that "the male head kept its usual reaction towards the female . . . when transplanted to a body of opposite sex" than that the body should acquire a new reaction as a result of the operation.

The complaint that Dr. Finkler had refused to submit his specimens for investigation by others was not mine, but was made, as I stated, by his German critics. The specimens which Mr. Boulenger brought to London have been repeatedly exhibited here. I was told that they were not to be submitted to dissection or section-cutting, but I am now informed that no such condition was imposed by Dr. Finkler in handing over the specimens.

Biology and Religion.[1]

By Prof. J. S. HALDANE, F.R.S.

FOR religion the world, whether visible or invisible, is the manifestation of God. The real basis of religion lies in our own conscious experience, in our awareness of values which determine the course of our existence and unite us all but cannot be regarded as derived from either individual or collective self-interest. In so far as we realise these values, their objective reality, and their unity, we acknowledge, whether we are aware of it or not, that our universe is a spiritual universe and the manifestation of one God.

The theories of natural science seem to recognise neither objective ethical values nor God. Yet many scientific men have been deeply religious, and in one way or another have, even though often unsatisfactorily, reconciled their science with their religion. With the progress of science in recent times such reconciliation has seemed to become more and more difficult, and the existence of spiritual reality in the sense implied in religion has seemed to become more and more shadowy. During the nineteenth century this process was very marked; and it was particularly the progress of biology, and only to a minor extent that of historical criticism, that brought the difficulty to a head. I shall endeavour in this paper to indicate what seems to me the cause of the difficulty, and to maintain at the same time that however uncompromising the attitude of biology is, and I hope always will be, towards obsolete details of theological creeds, there is in reality nothing to come between biological science and real religion.

Perhaps we can best realise the cause if we call to mind the argument of a once popular book, Paley's "Natural Religion." Paley argued that, first, the human or animal body is a piece of exquisitely perfect machinery; and that, secondly, the existence of this wonderful machinery is clear evidence of the existence of a superhuman Designer. His argument was not very original, but it was at any rate put with great clearness. The first step came to be accepted by the great majority of physiologists; but the second step was invalidated by the discovery of evolution and the theory of natural selection. It is, however, to the first step that I wish to direct attention; for the essence of the whole matter is there.

Granted that the body is a machine, Paley would have said that the soul is placed within to control its voluntary working. Nevertheless, the more the matter has been investigated the more clearly has the fact seemed to emerge that the conscious control of the machine is dependent on exactly the same sort of material conditions as its ordinary unconscious working. We need only, for example, reduce the oxygen supply, or cut off the supply of some substance supplied by a gland, to produce not only loss of normal conscious control, but also a condition akin to, or identical with idiocy. If, therefore, the body depends upon mechanical conditions, so also does the mind or soul. Moreover, moral and mental characters are just as clearly transmitted by ordinary generation as bodily characteristics. In Paley's time, and indeed for long afterwards, many physiologists believed that there is active in the liv body a factor which they called vital force, whic independent of the mechanical conditions. But observations just quoted are fatal to vitalism also.

Paley's first step, taken in conjunction with further development of physiology, thus leads straight towards what is called materialism. C sciousness becomes a mere mysterious accompanim of mechanical processes; and spiritual values ha ultimately no more meaning than they can have in purely physical world.

Paley was a product of his time. With his generati and succeeding generations, he accepted the assun tions about the nature of visible physical reality wh had come down to him from Galileo and Newton. Th assumptions were that visible reality consists of s existent bodies separated from one another in s existent space and time, and acting on one anotl according to the definite laws of mechanics, physics a chemistry. The human body, as a part of visible reali must be just as much subject to these laws as inorga bodies.

But Newton's conclusions about visible reality w based on the observation of inorganic phenomena. Th seem to fit these phenomena, or at least seemed un recently to fit them, though Newton himself was from thinking that he had done more than make beginning of applying them in detail. But do they the phenomena of life? If they do not, then Pale first step was a false one, and the materialistic c clusions which have so naturally grown out of it fall the ground. From the purely scientific point of vi of biology itself, the question is fundamental. one can doubt that the conception of a living organi as a mechanism such as Paley depicted is to a very la extent useful and convenient; but is such a concepti consistent with the characteristic phenomena of l and conscious behaviour? To this scientific questi I have largely devoted myself since my student day

If we observe the relation between physiologi stimulus and response we find that, under standardis or "normal" conditions of environment, the respon follows the stimulus as regularly as any physical effe follows its cause. But when the conditions of enviro ment are altered, perhaps to only a very slight degr this is no longer the case: the response is altere perhaps totally prevented or "inhibited," to use physiological term. The exact response of a lim for example, to a stimulus, say a visual stimul acting on the body, depends on a host of stimuli varyi in nature with the relative positions of the various par of the body: depends also on endless other co-existe stimuli, whether visual or of other kinds. It is just t same with chemical stimuli acting on any part of t body whatsoever.

When we regard this phenomenon from a wid point of view, we see that we can with very considerab success predict what happens if we assume that the li of an organism is something which actively asserts an maintains itself, including the organism's relations to i environment, in a manner which is specific or "normal

[1] From a paper read at the Conference of Modern Churchmen, at Oxford, on August 28.

responses and their modifications or inhibitions fall into intelligible order. Apart from this assumption, characteristic physiological responses are nothing but unintelligible chaos: we cannot predict the characteristic manner in which stimuli and responses become associated and effective.

That the parts and activities of a living organism exist relatively to one another is evident. The very nomenclatures of biology presuppose this. Relativity reigns supreme in biology. But not only is this so: the relationships of life also actively assert and maintain themselves. The responses of the nervous system become intelligible from this point of view; but this is still more evident in connexion with the simpler responses within the body to molecular stimuli—the responses connected with respiratory exchange, assimilation and secretion. It is with these responses that my own experimental work has been mainly associated, and the study of them has left no doubt in my mind of the necessity for regarding the already defined conception of life itself as fundamental in biology.

Perhaps this necessity will become more easy to understand if I refer to the basis of practical medicine in its therapeutical side. When the organism is injured by any passing cause, tissues of exquisite delicacy have been destroyed or altered in structure. We have no means of repairing or replacing these structures as we might repair or replace the injured parts of a machine. Nevertheless, the injuries can be healed, and by various means we can facilitate the process or render it certain. It is because life actively maintains and reproduces its normals that recovery is brought about. What a doctor does is merely to aid Nature in the process. Any other view of the matter amounts to mere quackery which has been repudiated by scientific medicine ever since the time of Hippocrates.

But I can almost hear some well-meaning scientific colleague saying "Your conception of life may be all very well as a sort of heuristic principle, but it is totally unintelligible. The process of healing and reproduction must depend on a series of molecular reactions; and the right way to understand it is to investigate these reactions one by one. Since the living body is material it must be subject to the laws of all material action. In other words, it must be a mechanism, though a very finely balanced and complex molecular mechanism." Let us then suppose for the moment that this is so, and see how the assumption works out.

The living body reproduces itself from generation to generation. In the process of reproduction it grows from a microscopical speck, or rather two microscopical specks, the male and female elements, which have united to form one. Little or none of the assumed molecular machinery can exist in these specks: it must all be gradually built up again in the course of development. This development itself is a very complex process, which on the mechanistic theory would necessitate the existence of extraordinarily complex molecular machinery in the germinal specks, and corresponding machinery in the parent organisms for producing the germinal machinery. The mind recoils from the incredible complications involved.

Specific germinal cells in the bodies of animals can sometimes be followed in their successive divisions from one generation to another, and in this sense there is continuity of the germ-plasm. On the mechanistic theory, therefore, the molecular machinery of reproduction reproduces itself by fission from its like. But how is a delicate piece of machinery to reproduce itself by fission? Imagine the unspeakable confusion in such a process, or in the sexual union of two similar pieces of machinery!

I have perhaps said enough to show why I cannot regard the mechanistic theory of life as tenable. It involves quite impossible assumptions and leads us nowhere in respect of the characteristic phenomena of life. Not only the newspapers, but also scientific men, continue to speak of the mechanism of life and heredity: I confess that such an expression has no meaning whatsoever to me. We cannot dispense with the distinctive conception of life. Let there be no mistake, however, about what this implies. It implies that the old conception of visible reality which Galileo and Newton set forth has broken down; and that there is no use in appealing to that conception in support of a mechanistic theory of life. Life would be unintelligible on that conception; but it is reality that science has to deal with, and not an ideal world of mechanism. The ideal mechanical world of Galileo and Newton corresponds sufficiently well for most practical purposes with our experience of inorganic phenomena, but does not correspond with our experience of biological phenomena. The supposed self-existent bodies and separable reactions of the ideal mechanical world have turned out to be not really self-existent and separable; and we have to modify our fundamental conception of visible reality accordingly, though for many practical purposes the merely mechanical conception may suffice.

It may be many years before the significance of the phenomena of life for our conceptions of visible reality is generally understood; but assuredly this general understanding will in time be reached.

So far I have only discussed life in such a form as we seem to meet with in plants, or in the activities of parts of our own bodies which we assume to be unconscious. I now come to conscious activity. We know what conscious action is in ourselves, and we can easily infer its presence or apparent absence in other persons. We can also form some judgment as to its presence in even lowly organised animals.

Conscious is distinguished from unconscious experience or activity by the fact that a conscious experience or action carries with it an ordered reference to both past and anticipated experiences, as well as to other present experiences. It was Kant who first pointed out this fundamental fact clearly in relation to perception. A conscious experience not carrying in itself ordered relations to past and anticipated experience is a purely imaginary figment. This discovery constitutes the great advance which Kant made beyond Berkeley and Hume. We cannot derive our conceptions of the spatial and temporal orderliness of our world from separate experiences of it: the orderliness is already given in any experience, and belongs to it. An ordered universe existing apart from conscious experience of it would be nothing to us. It was to a world of relativity that Kant's analysis of perception led.

At first sight Kant's idealism seems to lead us into impossible or practically unmeaning conclusions; but let us follow the same line of reasoning further than

Kant followed it. He belonged to his own time. The order which he found to be implied in conscious experience was simply the order of the physical world as pictured by Galileo and Newton; and indeed his idealistic philosophy became a sort of buttress to their ideas of visible reality. Whether visible reality was self-existent, or relative, or ideal did not seem to matter much in practice, although with relativity physics Kant's reasoning has now come into prominence among physicists themselves.

When we examine our own conscious experiences and actions we find that they hang together in another manner besides those pointed out by Kant. They hang together or are essentially related in the manner already described in connexion with the phenomena of life. Whether we will or no, they influence and inhibit one another in a manner which cannot be predicted or understood on merely physical principles, and which only becomes more or less predictable or intelligible in the light of the conception of life. What Locke called the secondary qualities in experience come under this category, together with various natural appetites and instincts, repulsions and attractions. Into all our conscious perceptions and actions this element of relatedness enters, and not merely the relatedness in a physical sense, to which Kant directed attention. Both in connexion with ourselves and with other organisms is this true. It is only by a process of artificial abstraction that we can neglect the biological aspect of our conscious experience, and the neglect of this aspect has led to endless intellectual confusion.

We must not make the mistake of supposing that the conception of life stops short at the body-surface of an organism. A living organism cannot be separated in thought from its environment. In life the physiological relation to environment is maintained just as clearly as the physiological relation between the parts of the body. An organism belongs to its environment just as much as its parts belong to one another. Different individual organisms are also organically related to one another, by parenthood, sex relations, and mutual association of various kinds. The normal limits in duration of individual life are also an apparent evidence of this relationship.

In consciousness of the biological aspect of experience, and in corresponding conscious action, our lives have for us a past and future which is inseparable from the present. Our perceptions and actions are thus those of conscious interest, as distinguished from the blind immediacy of what we regard as mere biological phenomena. Our world is a world of interests and values, and our actions have a corresponding responsibility attached to them.

The existence of biological phenomena showed us that a mere mechanical conception of visible reality is fundamentally inadequate, however useful practically for some purposes. The progress of philosophical investigation since Descartes has also shown us that in whatever way we may for temporary practical purposes represent to ourselves the visible universe, it cannot be in reality anything but a universe of conscious existence. Berkeley, Hume, Kant, and their lineal successors have been in agreement about this, however short they may have stopped in the further development of their conclusion. Putting together this conclusion with the previous one, we find that our universe is a univ of perceived interests and values, and of responsi conduct.

Let us now examine further the nature of the intere and values which present themselves in perception a conscious behaviour. We can think of them in the fi place as the interests of an individual human organis In the life of a conscious organism, what is required the maintenance of its normal organic life and struct is foreseen and provided for in the light of past exp ence, since conscious experience and action reach o as Kant showed, into both the past and the future. this process the environment is as much concern as the body of the organism itself, since life, when investigate it, involves, and indeed manifests itself a normal relation between living organic structure a environment. This fact is to some extent masked higher organisms, which, as Claude Bernard first in cated, possess, in the form of their blood, an inter environment which by various means is kept amazing constant in its character, and acts as a sort of buf between the living tissues and the variations in t external environment; but now that physiologists ha become aware of this, the true relations betwe organisms and environment are standing out ever m clearly. It is a relationship which can only be comp hended as an organic one: a merely physical interp tation of it is not possible. Even from the point f view of our merely individual lives, our environment in no mere physical relationship to us: it is bone of c bone and flesh of our flesh.

An isolated individual human organism is, howev only a scientific abstraction: for without at least mother or nurse no human infant could survive. In t perception more particularly of human relationshi and corresponding actions, we become aware of wi interests than those centred round our individ organisms. The wider interests centre round fam countrymen, the human race, and extend also animals, plants, and country. They extend also both the past and future. In the experiencing of the it is just reality itself that is being revealed to us; a spiritual reality, not merely ideal scientific abstractio We are, in fact, no mere self-centred beings, comple in ourselves; and those who set before themselves, a endeavour to act on, the idea that they are entire self-centred are only doing violence to their own natu

This latter conclusion seems to me equally cle even if we simply regard human behaviour from abstract biological point of view. A higher organism an assemblage of countless individual cells; but t behaviour of not one of them is intelligible biological apart from its relations to the rest, and to the enviro ment generally. In exactly the same way the biologic behaviour of individual human organisms is unintel gible apart from their relations to other hum organisms and the rest of their environment. The very being in the biological sense manifests itself this relationship. We belong in the most intima sense to our environment.

The wider interests which reveal themselves in huma society have a compelling power which dominates wh we regard as mere individual interests. In these wid interests we meet with something which we can in th sense describe as "not ourselves," though in anoth

ense it is the reality of ourselves. It binds us together spirit, so that what others feel and see we also feel nd see. We thus attain to what we regard as objective perception, a perception that others share in, and nat unites all men: also to corresponding objective tandards of behaviour.

This perception and behaviour is not just the collective or average perception and behaviour of a number f individuals, but something which only shows itself n fellowship with others, and in the contemplation of ur relationship with Nature. It is the manifestation f the spiritual Reality of our universe—the Reality which men call God.

We are so accustomed to regard reality as physical eality in the sense of Galileo and Newton that any more dequate conception of reality seems to us far away and nreal—mere mysticism. We are the children of a naterialistic age. We look for a soul consisting, if not f ordinary matter in the mechanical sense, yet of omething which is only a thinly veiled imitation of it. We look, also, for a similarly constituted God. Such ntities can never be found. God is with us, in us, and verywhere around us, as Jesus taught. We must earn to see spiritual reality, and not the mere appearnces of matter. We must learn, also, that the voice f God is not a voice threatening us from outside with naterial punishments or coaxing us with the hope of naterial rewards, but a voice which, when we hear it, ransforms our most hidden motives and thoughts.

Let me return to the relations of biology and other branches of natural science to religion. Perhaps it might seem that what I have been saying attributes to natural science the responsibility of blinding us to spiritual reality. Are not, for example, Galileo and Newton, and the great biologists who have treated the living body as if it were a piece of mechanism, responsible in this respect? To point out that theologians are equally responsible does not answer this question. I wish to consider it directly.

When we examine the original contributions of great men of science we always find, first, that on the data before them their conclusions were justified, and, secondly, that these conclusions were calculated to be of great practical use to their fellow men. If it is true that the reality of our universe is spiritual, it is no less true that we are constantly struggling with illusion and imperfection, and that it is only in that struggle that spiritual reality manifests itself to us. We cannot separate faith from works. The motive of science has always been the discovery of what, in one way or another, will be of use; and at every turn we make use of scientific discovery in practical affairs. It does not matter how limited in scope the discovery may be, we can always make use of it. To take examples, the discoveries by Kepler of the mechanism by which images are focussed on the retina, or by Harvey of a mechanical process by which blood is circulated through the body, were limited in scope, but of immense practical service. The eye cannot be regarded as a mere mechanical structure, nor the circulation as a mere mechanical process, so there is a reality beyond these discoveries. This does not, however, detract from their value, any more than the discoveries of Einstein have detracted from the value of Newton's discoveries.

Scientific investigation is just part of the struggle in which spiritual reality manifests itself; and the realisation of this brings science, particularly pure science, very near to religion. It is only when science becomes dogmatic that it assumes an attitude which seems to deny the existence of spiritual reality. We find very little of this dogmatism in the writings of great men of science, but much more of it in the desiccated science of systematic text-books and popular expositions. For example, the idea is spread abroad in such writings that natural science, unlike philosophy, advances by a steady process of addition. We have only to look back on the history of natural science to see how utterly misleading this idea is. The progress of science is just as much strown with the remnants of discarded theories as is the progress of philosophy; but, in spite of this, continuity of development is evident in the histories of both of these subjects. Surely it must be the same with theology.

During most of my life I have been struggling more or less with scientific dogmatism, but I have never before addressed an audience mainly clerical. I wish to take the opportunity, therefore, of adding my voice to those of others who are engaged in struggling with the shackles of theological dogmatism. There are very many who, like myself, are kept away from existing churches by creeds and church services which they cannot honestly countenance, and perhaps a still larger number who are actively hostile because they regard churches as hotbeds of superstition. If I thought that my country could get on equally well without churches I should not care what was taught in them. But I do not think so. We need to be constantly reminded of that spiritual reality which manifests itself in willing service of every kind, and without the perception of which our country would relapse into chaos.

The churches cannot afford to be hampered by unintelligible beliefs which are mainly materialistic accretions of Christianity and greatly weaken its influence on those who are worth influencing. Religion itself stands on ground which cannot be assailed: it has no use for rickety defences. The story of Jesus and His teaching appeals to all men, and influences them practically, because it touches what is deepest and most real in them. Many, however, feel forced to conclude that that teaching was based only on emotional illusion. Hence adequate philosophical or theological support is needed for it. This support should be based on the widest philosophical and scientific knowledge. Any shirking of the questions involved, or cowardly sheltering behind mere traditional authority, is fatal. The true function of a church is to help men to see reality as a whole, and to guide their actions accordingly, thus preventing social chaos, intellectual confusion, and artistic decay.

You are members of the national Church of England, and we are meeting near the spot where one of the greatest leaders of that Church, a man of English yeoman stock, met his end. It is to Latimer that my mind goes back when I appeal for intellectual freedom in the English Church. He stood, not only for social justice and humanity in his country, but also for intellectual freedom. It was not of his own sufferings, or his own soul, that he spoke as he was dying, but of the England he had served so fearlessly, so lovingly, so faithfully, thus finding oneness with God.

The candle which was lighted in England as Latimer and Ridley perished is still burning.

The Forces which lift Aeroplanes.[1]

By Prof. V. K. F. Bjerknes, Geophysical Institute, Bergen.

THE forces which carry aeroplanes are now subject to intensive experimental and theoretical investigation. In one respect, however, these investigations have led to a surprising result, namely, that the force which makes flying possible belongs to a group of forces discovered long ago, before the period of aviation. Their existence had been predicted mathematically, and these predictions had been verified by experiments.

The Direct Geometric and the Inverse Dynamic Analogy between Hydrodynamic and Electromagnetic Fields.

This old theory, and these old experiments, relate to what is called *hydrodynamic actions-at-a-distance*. The period when the doctrine of action-at-a-distance was absolutely predominant lasted, at least on the Continent, until about thirty years ago. The researches which I am about to describe, date from that period. My father, C. A. Bjerknes, could not reconcile himself with this doctrine at the time when he was a student at the University of Christiania, about eighty years ago. Ten years later he had the opportunity of acquainting himself with recent results of research in theoretical hydrodynamics. These had just led to a surprising fact: a spherical body could move through a frictionless fluid without experiencing any resistance. This paradox was in his eyes an important fact in discussing action-at-a-distance. The doctrine of Newtonianists had been that space was empty. They believed that a medium filling it would ultimately stop every motion. But this argument now turned out to be erroneous. The supposition that space was filled with a medium was not contradictory to the first axiom of dynamics, the principle of inertia. This made another idea occur to him: Should not the same medium be able also to propagate actions from body to body, thus giving rise to apparent action-at-a-distance? And would not the answer be found by solving the problem of simultaneous motion of two or more bodies in the fluid—for mathematical simplicity of spherical or cylindrical form?

The conditions under which my father worked were not favourable. But he never gave up his point of view, and twenty-five years later he was in possession of the full solution of the problem, and had verified the results by a series of striking experiments.

The result was that a very remarkable analogy became evident between the field of motion in a fluid and the electric or magnetic field of force: the bodies produced fields of motion of precisely the same geometric structure as static or stationary electric or magnetic fields. Moreover, they exert apparent actions-at-a-distance upon each other, equal to, but—most curiously—opposite to the actions-at-a-distance between the corresponding bodies in the electric or magnetic fields.

General Statement of the Analogy.

In one respect, however, my father's theory was special: he had proved this analogy to exist only for bodies of spherical or cylindrical form. By slightly changing the problem, I succeeded some twenty years ago in giving an absolutely general proof of the analog I retained in my theory the idea that the main fluid w homogeneous and incompressible. But for the sol spheres and cylinders I substituted *fluid* bodies of ar shape. These bodies may differ from the surroundin fluid in four respects: (1) In density: this gives th body a reaction against acceleration, different from tha of the surrounding fluid; (2) in compressibility: th bodies may perform motions of expansion and co traction; (3) the motion considered was allowed to b vortical inside the bodies, while it was always irrot tional in the surrounding fluid; (4) external force ma act upon the elements of the bodies but not on those the surrounding fluid.

The advantage of considering the entire system a fluid is that its dynamics are then determined com pletely by the hydrodynamic equations. Therefo the analogy to the electric or magnetic field may b demonstrated by a simple—in reality very simple—transformation of these equations. The leading ide of this transformation is to consider the actual flui field of motion as made up by two partial fields: th *impressed field*, which is that produced by extern force, including the hydrodynamic actions-at-a-distance and the *induced* or *free field*, which is due to flui pressure, setting aside that part of the pressure whic produces the hydrodynamic actions-at-a-distanc The impressed field exists only inside the bodies, whil the induced or free field pervades all space, includin that inside the bodies, and when added to the impresse field in this inside space, it gives the actual fields c motion of the bodies.

This system can be compared with an electric o magnetic one. Specific volume will then correspon to magnetic permeability or specific inductive capacity velocity will correspond to magnetic induction o electric displacement. The product of velocity int density, that is, specific momentum, will correspond t magnetic or electric intensity. Impressed field withi the fluid bodies will correspond to impressed field in th interior of a permanent magnet or a pyro-electri crystal, and induced hydrodynamical field will corre spond to induced magnetic or electric field in externa as well as in internal space. Velocity of expansion o of contraction will correspond to magnetic or electri charge, positive or negative; and vorticity, specially defined here to be the curl of induced specific momentum will correspond to electric current density.

This correspondence between the quantities used fo describing the two kinds of fields being agreed upon the analogy between the two kinds of fields may b stated thus:

At any moment the field of motion of the fluid systen is identical in geometrical structure with a certain stati or stationary magnetic or electric field; and in thi hydrodynamic field there are apparent actions-at-a distance which, element for element, are equal but opposit to those of the corresponding forces of the magnetic o electric field.

Having obtained this theoretical result we can easily apply it to solid bodies; for the external force which w have introduced is subject to no restriction. We can

[1] From a discourse delivered at the Royal Institution on Friday, May 9.

herefore let this force, or a certain part of it, control he motion of a body in such a way that it moves as if it were rigid, or solidly elastic. This result is attained by imagining reciprocal actions between the particles of the body which have no resultant for the entire body. The only thing to be taken into account will be the impressed fields produced by these reciprocal actions between the particles. But as these fields are characterised by small motions in all possible directions, they will in general give rise only to insignificant reactions with the exterior field.

By substituting solid bodies for the fluid bodies we can obtain experimental demonstrations. But, it may be argued, where solid bodies are moving in a fluid we do not in general observe any striking analogy with the phenomena of the electric or magnetic fields. The reason for this is twofold. First, to recognise the analogy we must divide the field into its impressed and induced parts. The distinction between these two partial fields will not in general be visible to the eye. It must be found by a dynamical analysis. Secondly, the hydrodynamic system is a moving system which is always changing its configuration, and the direction and intensity of motion of its different parts. During each new phase of its motion we must therefore compare it with a new electromagnetic system: this gives a fugitive character to the analogy. But in two cases it must crystallise into a concrete and strikingly visible form: first, when the motion is permanent, and secondly, when it consists of small synchronous oscillations about an invariable average configuration. In both cases we have to compare it with a constant electric or magnetic field. In both cases the induced hydrodynamic field is hidden as a more or less invisible field, while that part of the impressed field which is due to the hydrodynamic actions-at-a-distance produces strikingly visible effects.

This result is, however, obtained in both cases at the expense of a certain reduction of the extent of the analogy. As vortices cannot be oscillatory in a frictionless fluid, they must be zero. In the oscillating case, therefore, the analogy with the electric currents fails. On the other hand, as displacement of the boundary surface would violate the permanence of the motion, all phenomena due to change of volume or of place of the bodies drop out; and we retain only the phenomena depending upon permanent circulation, corresponding to those of electric currents.

The Instruments.

A general auxiliary instrument is a generator for producing vibrating motion. A little electric motor drives a spindle having two eccentrics, each of which works a little pump. Each pump is double-acting and consists simply of cylinder and piston but has no valves. Through the outlet tubes communicating with the ends of the cylinders a few cubic centimetres of air is thus alternately driven out and in, in opposite phases from the two ends of the same cylinder. A cock allows us to regulate the amplitude of that oscillating air current which is conveyed to the main instruments. When a unidirectional air current is desired, a simple valve arrangement may easily be inserted.

A practical peculiarity of the instrument is that the cylinders, not the pistons, are connected with the eccentrics, and that the pistons react against the motion only by their inertia. This proves useful in connexion with the regulation of the amplitudes. Cylinder and piston are carefully polished but *never* oiled. Another peculiarity of construction is an elaborate symmetry of the moving masses and of their motions, in order to eliminate all vibration of the instrument by compensation.

The alternating air currents from the generator are used to produce two kinds of vibration: first, pulsations, or periodic changes of volume, and secondly, oscillations or periodic changes of place. The pulsating body is a drum having metallic membranes (by their durability preferable to indiarubber membranes) and fixed on the end of a metal tube (Fig. 1, I, II). The membranes are alternately blown out and sucked together by the alternating air current. Loading one membrane of such a pulsator, and connecting the other membrane with a spherical shell, which is mounted on a tube and surrounds the pulsator, we get an oscillator (Fig. 1, III): the outer shell and the inner load make opposite oscillations. The desirable case when these become equal amplitudes is attained when the weight of the load equals the sum of the weight of the spherical shell and the half of the mass of water displaced by it. In this event the pulsator will, by the principle of the conservation of the centre of gravity, remain at rest, and the outer shell will oscillate undisturbed both when the projecting tube of the pulsator is taken in the hand and when it is inserted in a rigid clamp. It will not transfer disturbing oscillations to sensitive balances in which it is inserted for the experiments.

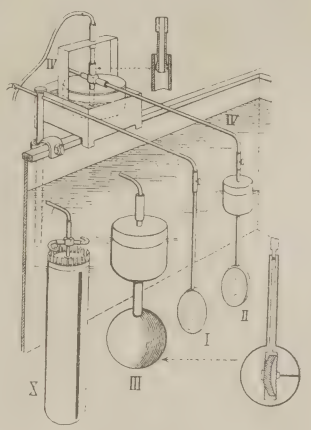

Fig. 1.—Balance arrangement with pulsators (I, II), oscillator (III), rotating cylinder (X).

Different arrangements can be made for giving such a pulsator or oscillator the degree of mobility required for examining the forces or couples exerted upon them. It is generally convenient to let it float with a buoy. If then the tube conveying the air from the generator is sufficiently flexible, we have at once both translatory and rotatory mobility. To reduce the mobility to a pure translational one, we may give the system of tubes which convey the air from the generator the form of a torsion balance. The weight of this balance is conveniently carried by a floating buoy, swimming in the tank used for the experiments, or in an extra vessel outside it, to reserve the main tank exclusively for the bodies under experiment. We may also do away with the torsion tube of this balance, and let the air go directly from a fixed tube through a loose joint into the balance with really very little loss of air (Fig. 1, IV). This has the advantage that the equilibrium is always indifferent. One of these balance arrangements may be used for demonstrating the attractions, repulsions,

or lateral displacements exerted upon a pulsating or an oscillating body. The latter may be inserted in the balance in two principal ways: for longitudinal mobility, so that its direction of mobility coincides with its axis of oscillations; or for transverse mobility, so that the direction of its mobility is normal to its axis of oscillation. Rotational mobility of an oscillator is obtained either by suspending it by a rubber tube, or by letting the air pass direct into the floating oscillator through a loose joint.

As bodies having no vibrating motion of their own, we use a heavy sphere suspended from a float, a light sphere held under water by a load and suspended from a float, a light and heavy cylinder suspended in the same way.

Finally, for studying the field of motion set up in the fluid we may use a simple arrangement, namely, a light spherical body attached to an elastic wire. This sphere will be set into induced oscillations by the surrounding fluid, and, choosing that period which gives resonance, we can magnify the minute water oscillations and mal them visible. The sphere may also carry a light r which projects above the surface of the water, ar carries a pencil which inscribes its oscillations aut matically with ink upon a glass plate placed above t water.

These instruments serve for experiments wit vibrating bodies. Permanent motions can be produce by the rotation of cylindrical bodies. By a simp valve arrangement inserted in the tubes conveying t air current from the generator, the alternating curre may be changed into a unidirectional one. Th current can then be used to drive a turbine attached t a cylinder which is thus set into rotation (Fig. 1, X). T examine the forces exerted upon such a cylinder th latter is placed in the balance just as the pulsator o oscillator was, while another cylinder driven in th same way is mounted on a handle which may be take in the hand or fixed in a support.

(*To be continued.*)

Obituary.

Sir William Bayliss, F.R.S.

"BAYLISS'S book is by far his greatest contribution to science—much more important than any of his individual discoveries is his statement of his point of view." These were substantially the words used to me by a very competent critic. At the time I wondered whether or not it were so, and I have often wondered since. Bayliss's investigations into the electric phenomena of the heart [1] and the salivary glands,[2] into the conditions which govern the cerebral circulation,[3] into the muscular movements of the alimentary canal,[4] into the mechanism of vaso-dilatation,[5] into the correlation of vaso-motor reflexes;[6] his establishment of the existence of antidromic fibres in the mammal,[7] his researches on the application of surface phenomena to physiological action,[8] and the discovery of secretion [9]—these were his principal discoveries.

When all allowance has been made for the fact that most of this work was carried out in collaboration, it remains an extraordinary tribute to a man's point of view to say that the statement of it transcends such researches. Yet in support of my friend's statement I reflect that in another continent there are "Bayliss Clubs"; these do not exist for the study of the specific subjects enumerated, but for the joint discussion by physiologists and chemists of so much of science as they have in common. The association of Bayliss's name with such societies is a tribute precisely to Bayliss's statement of his point. It is not merely that when one asked why the clubs were so called one received the answer, "We discuss the sort of thing which is in Bayliss's book," but that when one comes to think the matter out, one finds it not a little surprising that such societies were not associated with other names; for it cannot be claimed that Bayliss was a pioneer in the investigation of biochemistry.

[9] *Journ. of Physiol.* 28. 325, 1902, and 29. 174, 1903.

His interest in the subject—so far as may be gleane from his published works—dated from about the com mencement of this century—before which date th pioneer work in Great Britain had been done. Hard had launched colloid chemistry in the 'nineties Hopkins, before the eighteen hundreds were complete was well forward with that series of isolations whic adorn both organic chemistry and physiological science and Halliburton had done the major portion of hi work.

Bayliss's great contribution was that he discusse the whole subject of biochemistry as a continuou whole, thinking out each point *ab initio*, and com mitting the record to paper, so that what he though for himself he thought also for others. His method o approaching a subject was one which lent itself admir ably to this procedure. The quality of genius differs from individual to individual, probably even more tha its quantity. Among scientific men, the genius of som is of the artistic type; though possessing great cer tainty of touch their inspiration comes they know no whence. To the onlooker it appears almost to be ar accident; that it is not so is proved by the fact tha it crops out too often in the life of the same person In others genius is of the mathematical type; with them the premises are grouped in a particular way and in their vision the conclusion flashes out.

Bayliss's genius was not precisely of either type—at least if my own appreciation of it may be trusted. He took nothing for granted, he inquired with meticulous care into every step of an argument; if he found some thing which was not perfectly clear to him, he spared no pains to discover whether the thread of the argu ment was really broken or whether he had merely failed to follow it. In the end his mind became clear on the subject; to his own satisfaction he was able to pronounce either that he understood the matter and that it was thus, or that he failed to understand it because the thread, to the best of his judgment, was not continuous.

Such a method is eminently calculated to exclude all forms of obscurantism, and indeed nothing was more

reign to Bayliss's philosophy than vague talk about vital force" or the like. Either a phenomenon was derstood, in which case the explanation could be itten down and placed on record in his book, or it mained for investigation. In the latter case it might ll into one of two categories, (*a*) that of being capable explanation on the basis of current knowledge of the operties of matter, (*b*) that which awaited further scoveries into the fundamental conditions which vern material things. It was Bayliss's good fortune be at the zenith of his intellectual powers at a time hen important additions were made to the knowledge several departments of chemistry and physics, such, r example, as of adsorption, of catalytic action, of terfacial phenomena, and of radiant energy. Each ccessive addition afforded to Bayliss a prospect of e removal of phenomena from category (*b*) (above) to tegory (*a*), and of their final elimination from the gion of the unexplained. That was Bayliss's point of ew—as I understand the matter; it was a point of ew extremely stimulating to the student, not only ecause it led so directly to experimental investigaon, but also because it led along a road which emed so straight and so easy to follow.

Could Bayliss have been given the choice as between spectacular form of genius on one hand and a form hich was readily intelligible on the other, I feel sure e would have chosen the latter. The spectacular had ttle attraction for him; simplicity was characteristic less of his intellectual outlook than of his personal abits.

I gladly concede to rising generations that to them ayliss's statement of his point of view is his most nportant work, but to myself Bayliss—of course in onjunction with Starling—was pre-eminently the iscoverer of secretion. The moment when the first rop of pancreatic juice was elicited by the injection of uodenal extract must, I think, have been the most ramatic in his scientific career. Possibly I take this iew, because I was at a peculiarly impressionable age t the time, possibly it is accentuated because of a rifling incident which stamps it upon my mind. I had he good fortune to witness, not indeed the first successul experiment on the subject, but I think the second —that in which the first was to be either confirmed or efuted. The physiological laboratory at University ollege, London, was in those days peculiarly open to oung physiologists—I imagine that it is not less so iow. Some errand took me round there: the door of Bayliss and Starling's room was open: an experiment vas in progress. Bayliss held a flask in one hand, and vith the other was in the act of introducing a tissue xtract into the circulation from a burette, Starling was n his haunches, his eye on the level of a canula which rojected from the animal: the extract went in: the lood pressure fell for the nonce: there was a pause and hen—drop, drop, drop from the canula. There was no ecrecy—all was explained without reserve, to a man vho had published perhaps a couple of papers, vho hailed from another laboratory, whose very resence might have been accounted an intrusion, and vho had no possible claim on either the confidence or he genius of those who had made so great a discovery. Thus can generosity and understanding attract youth within the charmed circle of genius.

Indeed, Bayliss loved the company of young. I can see him now discussing some topic with a circle of young people, and, it may be, obscure physiologists, at the meeting of some society, and by his simplicity and sympathy wiping out the disparity in age and status, or lunching off porridge in a popular restaurant surrounded by young researchers and wishing for no better fare and no better company.

Bayliss took a considerable interest in public affairs —scientific, sociological, and political—probably in that order. Under this heading mention should first be made of his work in connexion with the Medical Research Council; for the following information I am indebted to Sir Walter Fletcher. From the historical point of view the Medical Research Council came into being at a time when the practise of medicine in Great Britain had much to gain from a closer liaison with physiological discovery—a fact which was greatly emphasised by the War, and one which afforded to Bayliss a field of peculiar usefulness in connexion with the work of the Council. The work which Bayliss did during the War will always associate his name with the subject of surgical shock, for the fuller understanding of which the Council appointed a very strong committee over which Bayliss presided; his own contribution was principally on the side of treatment. His introduction of intravenous injections of gum saline not only was regarded by many competent authorities as being of great use, but also it paved the way for a renewed interest in blood transfusion and a much improved technique for the purpose.

After the War, Bayliss assisted the Medical Research Council by presiding over a Committee for the investigation of the biological action of light, the object of "which is to analyse, explain, and extend all our valuable but still quite empirical knowledge of the action of light on the body, as in increasing its defence against tuberculosis, raising the bacteriological power of the blood, and in replacing and facilitating the action of vitamin A." Bayliss greatly assisted in suggesting precise laboratory observations. This work is still in progress, and in its concluding phases his loss will be greatly felt.

Much of Bayliss's work was of a surgical type; and, probably rather by accident, he was singled out at one time as the special target of those who disapproved of animal experimentation—a rather singular irony, because he was always on the side of the weak, the struggling, and the oppressed in all movements designed to better their condition. In politics he was a Liberal and presided over a local organisation of the Liberal party.

Bayliss's sociological interests became more evident towards the end of his life. The last man to derive any satisfaction from seeing his name in print, he was a frequent contributor to the press in the form of letters on such subjects as he thought might be helpful. This was part of his "statement of his point of view," though in a minor sphere; where he found difficulties he recorded them and gave the record to all and sundry who might be helped by it. On scientific matters he was a frequent contributor to NATURE, whilst his sociological writings embraced subjects so widely separated as the importation of cocaine, the methods of killing meat for food, and the desirability of birth

control. Indeed, he was a vice-president of the Society for Constructive Birth Control and Racial Progress.

Bayliss received the honour of knighthood in 1922. He held the following degrees and distinctions: M.A. and D.Sc. (Oxon.), Hon. LL.D. (Aberdeen and St. Andrews), F.R.S., Hon. Fellow of Wadham College, Oxford, Hon. member of the Danish Academy of Science, Corresponding Member of the Société de Biologie (Paris) and of the Royal Academy of Belgium, Professor of General Physiology, University College, London, member of the Council of the Royal Society, 1913–1915, secretary and afterwards treasurer of the Physiological Society, Joint Editor of *Physiological Abstracts* and of the *Biochemical Journal*. Bayliss, with Starling, delivered the Croonian Lecture to the Royal Society in 1904 and received the Royal Medal in 1911, the Copley Medal in 1919, and the Baly Medal of the Royal College of Physicians in 1917. He delivered the Oliver-Sharpey Lectures in 1918, the Sylvanus Thompson Lectures in 1919, and the Herter Lectures in 1922. JOSEPH BARCROFT.

AN appreciative account of the scientific career and work of Dr. T. C. Mendenhall, who died on March 22, is contributed to *Science* of July 11 by Mr. G. R. Putnam, and we are indebted to it for the following particulars: Dr. Mendenhall was born on October 4, 1841, and after preliminary training as a teacher, became the first professor of physics in the Ohio State University. He went to Japan in 1878 as professor of physics in the Imperial University at Tokyo, and three years later returned to Ohio. He was preside for several years of the Rose Polytechnic Institu and for seven years of the Worcester Polytech Institute, from which he retired in 1901. Dr. Mend hall took a leading part in many activities connect with science and engineering in the United Stat He was for five years superintendent of the Coast a Geodetic Survey, and served as president of t American Association for the Advancement of Scien and the American Metrological Society. He carri out some notable investigations in terrestrial gravit seismology, atmospheric electricity, and related subject

---

WE regret to announce the following deaths:

Mr. F. H. Bradley, O.M., fellow of Merton Colleg Oxford, and author of "Appearance and Reality "Principles of Logic," and other authoritative wor on problems of philosophy, on September 18, ag seventy-eight.

Prof. Alexander Darroch, professor of education the University of Edinburgh, aged sixty-one.

Dr. Franz Doflein, emeritus professor of zoolo and comparative anatomy in the University of Breslau on August 26, aged fifty-one.

Dr. J. Elliott Gilpin, professor of chemistry Johns Hopkins University, known for his work on t action of chlorides of phosphorus on amides and c fractionation by capillary diffusion of crude petroleu aged fifty-seven.

Dr. Sidney Martin, F.R.S., physician to Universi College Hospital, London, and distinguished r researches in chemical physiology and pathology, September 22, aged sixty-four.

Current Topics and Events.

A FINE, seated statue of Lord Lister, in academic robes, the work of Mr. G. H. Paulin, was unveiled in Kelvingrove Park, Glasgow, adjoining the University, on September 17, by Sir Hector C. Cameron, Dean of Faculties. The Lord Provost presided, and speeches setting forth Lord Lister's unique service to humanity in the domain of scientific surgery were made by Sir Hector, Sir Donald MacAlister, Bt., principal of the University and president of the General Medical Council, and Prof. J. H. Teacher, of the Royal Infirmary Department of Pathology, who is the custodian of the Lister relics there preserved. It was in the Kelvingrove Park, near his house, that Lister meditated the principles of his antiseptic method of wound treatment, during his tenure of the University chair of surgery from 1860 until 1869. It was in the Royal Infirmary, near the old College, that he applied these principles to practice, and thereby demonstrated their efficacy in the prevention of suppuration and of septic poisoning in operative wounds. The ceremony was preceded by a luncheon in the Civic Chambers, attended by a large number of distinguished surgeons and citizens of Glasgow, and by Mr. J. J. Lister, fellow of St. John's College, Cambridge, and nephew of Lord Lister. The latter spoke of his uncle's early researches, and of his private life, in response to the toast of the Lister family, proposed by Sir Donald MacAlister, who narrated some picturesque incidents of his friendsh with Lord Lister during thirty years. The stat completes the effort begun by the Glasgow List Memorial Committee in 1912, but interrupted by t War. Generous contributions have been made by i not only to the Glasgow monument, but also to t international fund for establishing a Lister Oratic and Prize for research in surgery, to the memorial Westminster Abbey, and to the Lister collectio displayed in the Glasgow Royal Infirmary in con memoration of the great surgeon's association wi the institution.

THE announcement in the daily press regarding t decision of the Government to provide a "further sum of 500,000*l.* for agricultural education an research deserves, perhaps, some elucidation. It ma be recalled that the Development Commissione hold two funds—the old and the new. From the ol come such charges as the grants to the variou Agricultural Research Institutes established befo the War and the salaries and expenses of the advisor officers attached to University Agricultural Depar ments. The old fund, also, has to meet the cost what may be termed the miscellaneous statutor activities of the Commissioners in relation to fishery harbours, etc. To the new fund, on the other hand being the creation of the Corn Production (Repea

ct, is debited the cost (in England and Wales only) certain schemes which escaped the fall of the eddes axe. As to finance, it would appear that the d fund is kept alive by annual doles from the reasury, whereas the new fund, starting with 30,000*l.* in 1921, has now received a windfall of a rther sum of 500,000*l.* In a communiqué recently sued by the Ministry, it is announced that the new oney will probably be allocated in part to the hemes relating to research on foot and mouth sease; economic research; marketing investigaons; veterinary education and research; soil rveys; and the National Institute of Agricultural otany. It is also announced that, in relation to the ew money, no definite allocation of funds as between cotland and England has been made. From this xplanation it would appear that the Corn Production New" Fund of 850,000*l.* is earmarked for expenditure England and Wales only.

ANNOUNCEMENT has been made of the retirement n September 30 of Dr. Crichton Mitchell from the rvice of the Meteorological Office, in which he has cted for some years as general superintendent of ne activities of the office in Scotland. He was riginally appointed from May 16, 1916, to be uperintendent of the Observatory at Eskdalemuir, n the recommendation of the Gassiot Committee of ne Royal Society. That committee is responsible or the administration of the Gassiot Trust Fund, the ost notable of the few private endowments for eophysical subjects in Great Britain, and on the ansfer of the administration in 1910 of the Obervatories at Richmond and at Eskdalemuir from ne National Physical Laboratory to the Meteoroogical Committee, it accepted the responsibility also f nominating superintendents of the three observaories attached to the Meteorological Office at which eophysical work was undertaken, namely, Kew, skdalemuir, Valencia. At the termination of his rst year, Dr. Crichton Mitchell was reappointed for ne duration of the War or longer if it were necessary. he appointment so begun has continued for eight ears and a half with great advantage to the obervatories and considerable enlargement of their cope. The work now includes the climatological ork taken over from the Scottish Meteorological ociety in 1913 and the expansion of the meteoroogical station at Lerwick into a geophysical obervatory, when certain buildings became available here after the War, as well as the work on daily eather at Scottish stations for the Air Ministry. r. Mitchell brought to his task the enthusiasm for hysical science engendered in the University of dinburgh in the time of Tait, Crum Brown, and hrystal, the practical experience of managing an bservatory at Trivandrum, and the administrative xperience of the educational department of Travanore. That he should have been available for eveloping his special gifts of organisation in Scotland ast in the dark days of the War must be regarded s an example of good fortune for the geophysical iences, which otherwise labour under considerable isadvantages.

THE *Morning Post* has discussed recently the question of why "science does not pay." It is true that in many cases technically trained men fail to make much direct use of the knowledge they acquire at college in their subsequent life. But we know that the scientific training they have undergone has indirectly often been of the greatest value to them. We are not impressed by the fact that sometimes a municipality offers a beggarly salary for a technically trained assistant. Unless the prospects are good, there is little chance of a suitable man being obtained. Young men like posts where there is a chance, even if only remote, of ultimately getting a lucrative and influential position. For this reason they are content to receive a less salary than a mechanic of the same age would be allowed by his Trade Union to accept. Even a Covent Garden porter demands a guaranteed minimum of 4*l.* 5*s.* per week, whilst many technically trained men accept readily initial salaries less than this. A junior engineer in works, even although he has had works experience, often begins on a less salary than the minimum given in the Burnham scale for secondary school teachers. But capable men have good chances of promotion to better posts, and if they are enthusiastic for their profession, they do not grumble even when promotion seems remote. The remedy for unemployment is the development of national resources, and this calls, as Prof. J. A. Fleming says in a letter to our contemporary, for new ideas, initiative, and invention. Many manufacturers are fully alive to this fact, and we think that nowadays they all hold science in high esteem. In the engineering profession, there is a demand both for young men of the public school type, that is, men who get on well with manual workers, and for thoughtful men who love research and invention. A young honours graduate in science with works experience has little difficulty in getting a post in the electrical engineering profession. We think that the chances of promotion compare very favourably with other professions. It has been suggested that the Engineering Institutions look after the remuneration of their members and are simply glorified Trade Unions. This is not the case. They were founded for the advancement of science and its applications, and only enforce regulations on those engaged in any advisory or consultative capacity.

CERTAIN of the delegates attending the International Congress for the Protection of Nature held in Paris at the end of June 1923, felt that the object desired could be better effected by means of a smaller and more permanent organisation. An informal conference was therefore held at the Natural History Museum on November 2, at which it was decided that the Society for the Promotion of Nature Reserves should summon a meeting of organisations in Great Britain interested in the protection of animal and plant life, the promotion of Nature reserves, and kindred objects. The meeting was held at the Natural History Museum on January 14, under the chairmanship of Viscount Ullswater, and as the outcome the Central Correlating Committee for the Protection of Nature was set up, and it is believed

that similar committees will be formed in other countries. The constituent organisations of the British Committee and their representatives are as follows: The Trustees of the British Museum, Lord Rothschild (chairman); British Ornithologists' Union, Maj. A. G. L. Sladen; Entomological Society, Mr. W. G. Sheldon; International Committee for the Protection of Wild Birds, Mr. Hugh Gladstone; Linnean Society, Sir Sidney Harmer; National Trust for Places of Historic Interest and Natural Beauty, Mr. E. G. B. Meade-Waldo; Royal Society for the Protection of Birds, Mr. F. E. Lemon; Society for the Preservation of the Fauna of the Empire, Maj. Stevenson Hamilton; Society for the Promotion of Nature Reserves, Earl Buxton; Zoological Society of London, Dr. P. Chalmers Mitchell. Dr. G. F. Herbert Smith, Natural History Museum, S.W.7, is the Honorary Secretary-treasurer.

THE new Anglo-Dutch telephone cable which connects Domburg, Walcheren, on the Dutch coast, with Aldeburgh has been successfully laid. The length of the cable is 86 nautical miles. Pupin coils are not used, but each of the sixteen conductors is continuously "loaded" with iron wire. The British Post Office and the Dutch Telegraph Administration are to be congratulated on having such well-founded faith in mathematical theory. Through such a long length of cable, speech would be hopelessly distorted were it not for the loading. Another novelty is the use of paper instead of gutta-percha or ballata for the dielectric. This reduces the leakage and lowers the electrostatic capacity, both highly desirable results As strong tides and currents prevail in the Channel and North Sea, substantial armouring in addition to two lead sheaths are employed. To obviate the necessity of having to make numerous joints, the cable was constructed in ten-mile lengths, and the s.s. *Faraday* was fortunate in having calm weather during the process of laying the cable. The weight of the cable exceeds 2000 tons, and Messrs. Siemens Brothers and Co. had to build a special shop and erect new machines in order to make it. The tests show that the cross-talk between the core circuits and between a physical and its associated "phantom" circuit were less than the minimum specified. It is hoped that a good telephone service between Britain and continental countries will foster trade and promote better political relations.

THE electrical transmission of photographs has been an accomplished fact for some time past, and the principle involved is simple. A very small pencil of light passes through the surface of a cylinder and impinges upon a photo-electric cell at its axis. The negative to be transmitted is wrapped round the cylinder, and as the latter revolves with a fine screw-like movement, every part of the negative passes in turn between the light pencil and the photo-electric cell and regulates the current according to its density. The receiver at the other end of the wire consists of a cylinder that revolves synchronously with the sending cylinder, and is covered with a sensitive photographic film upon which impinges a very fine pencil of light after it has passed throug a "light-valve" which allows light to pass throug it of an intensity that is regulated by the trans mitted current. It is but a step from the sendin of a simple photograph to the transmission of th three colour-records of a colour photograph. Thi we learn from the Colour Supplement of the *Britis Journal of Photography* for September has recentl been successfully done at the instigation of Mr S. H. Horgan over a line about a thousand mile long, namely, from Chicago to New York. Mr Horgan made a three-colour lantern slide from th records as received, and says that the Wester Electric Company were "amazed at the beautifu and faithful colours shown in the slide."

IN connexion with the British Empire Exhibitior the British Dyestuffs Corporation, Ltd., has publishe an illustrated booklet which tells the story of th discovery in 1856 of the first artificial dyestuff b W. H. Perkin, who was then but eighteen years old and of the subsequent vicissitudes and successes o the dyestuffs industry in Great Britain. Withi twenty years of that chance discovery, German had taken the lead among the dye-producing nations and Great Britain was importing 80 per cent. of he requirements from continental sources. The declin and fall of British initial supremacy in this field ha been attributed to many causes, but the author o this pamphlet is convinced that neglect of researc was the most potent. The renascence of the industr during the War, the energy and resourcefulness o the firms that had survived foreign competition, th establishment of the Corporation about five year ago, and the reversal of the 4 : 1 ratio of imports t home manufactures, are events and achievements too recent to have been forgotten by the scientific world but their reiteration from time to time to those wh can with difficulty understand the fundamenta importance of a vigorous organic chemical industr is both useful and necessary. It is interesting t note that since its inception the Corporation ha expended 450,000*l.* on research; that it now employ 125 chemists, 83 per cent. of whom possess high university degrees, 30 colourists, about 30 engineers and approximately 3000 workpeople. The fiv factories owned by it occupy 600 acres of land, an consume annually 80,000 tons of coal, 30 millio units of electricity, and 2000 million gallons of water Facts like these speak for themselves.

DURING recent years the Government of Grea Britain has been increasingly active in institutin measures for dealing with the diseases and pests o cultivated plants and crops, and J. C. F. Fryer an G. H. Pethybridge (*Journ. Min. Agric.*, July 1924 have drawn up a useful historical summary an résumé of the present position of the phytopathologica service of England and Wales. In the early years after the passing of the Privy Council orders against the Colorado potato beetle in 1877, all research an advisory work was dependent upon the efforts o individual scientific workers. No official service wa organised until the passing of the Development an

Land Improvement Funds Act, 1909, which provided resources for a definite scheme of research investigation and advisory work in agricultural and horticultural plant pathology. This service has developed into two distinct, but co-ordinated, organisations, one consisting of a body of Government officials under the direct control of the Ministry of Agriculture, and the other of a number of scientific workers in the various universities, agricultural colleges, and research institutes, financed from Government funds, but free from the detailed instructions of the Ministry and subject only to a certain amount of supervision to secure efficiency. The résumé indicates the subdivision of the work among the various units of these two sections. Diagnosis of diseases and pests in the field is the function of a corps of advisors, and investigations into fundamental problems such as those relating to the physiological action of insecticides and the nature of immunity and resistance to disease are carried on by the research workers in various institutions. The official body deals with the collection and distribution of information, the practical work of administering existing legislation with regard to diseases and pests, and the control of plants coming into or exported from Great Britain. Although each part of the service is independent, an increasing degree of co-operation exists in dealing with problems of all types, thus enabling more rapid and efficient progress to be made.

A PERIOD of frequent rainfall, which has prevailed over the British Isles since the commencement of April, is dealt with in the *Meteorological Magazine* for September by Mr. C. E. P. Brooks, of the Meteorological Office. The rainfall is given for the period of five months, April to August. The percentage of the average rainfall, 1881–1915, is given for different parts of the British Isles. The excess is least in Scotland, where for the five months it amounts to 126 per cent. of the average. In Ireland it is 131 per cent., in England and Wales 146 per cent., and for the British Isles generally, 138 per cent. of the average. For the south-east of England the fall is 161 per cent. of the average, and in each month with the exception of June the percentage of the average rainfall is greater in the south-east of England than in any of the larger divisions of the British Isles. The five months in question are said to have proved a decidedly rainy period, although not excessively so; the rains were chiefly cyclonic. Details are given showing the influence of travelling Atlantic depressions on the weather of the British Isles, an inquiry which some day may yield data to assist in long-period forecasting.

THE Chinese floods are somewhat explained in the *Meteorological Magazine* for September. The floods are referred to as unparalleled in the present century. It is stated that in the province of Chih-li 25,000 square miles are under water, and it is estimated that nearly five million people are homeless. The water is 3 feet higher than in the flood of 1917, when the material damage was estimated at 25,000,000*l*. Between Tientsin and the Shansi Mountains is the meeting ground of five rivers, and a great quantity of silt is brought down from the mountains; this raises the level of the river bed. The waters are greatly restrained by embankments, and if a gap is broken a river may flood a wide area of the country. The average rainfall is about 20 inches a year, which falls almost entirely in the three summer months July-September. This summer the rainfall has been abnormally heavy; at Pekin, the fall in July was 26 inches, and at Tientsin 32 inches fell in three weeks. These heavy rains have broken numerous gaps in the banks, causing disastrous floods over all the low-lying country. The meteorological situation favouring floods in North China is dealt with, and reference is made to an article in the *Times* of September 2, which alludes to definite plans having been prepared after the disaster of 1917 to avert the danger of similar floods.

IT is announced in the *Observatory* that Prof. H. Kopff, of the Heidelberg Observatory, has been appointed professor of theoretical astronomy in the University of Berlin and Director of the Astronomischen Recheninstituts.

A DIRECTOR of the Norfolk Agricultural Station is required. Candidates for the position must possess a university degree or diploma, a modern scientific training in agriculture, first-hand experience of arable agriculture, organising ability and facility in lecturing. The latest date for the receipt of applications, which should be sent to the Secretary, Norfolk Agricultural Station, 11 Bridewell Alley, Norwich, is October 11.

AN assistant is required in the British Museum Laboratory for research in connexion with the cleaning and restoration of museum exhibits. Candidates must be honours graduates in chemistry, with research experience and a wide general knowledge of chemistry, with, if possible, training in mycology and an interest in archæology. Applications for the post should be sent, upon a prescribed form, not later than October 11 to the Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1.

APPLICATIONS are invited for positions under the Ceylon Government of a mycologist and a systematic botanist. The first named, if a senior officer with tropical experience, will be placed in charge of the mycological division; the second will be required to take charge of the systematic work in the Botanic Gardens of the Colony, to make researches into the flora of Ceylon, and to study especially the ecology of Ceylon plants. The posts will become vacant about July next. Applications must be made upon a special form obtainable from the Private Secretary (Appointments), Colonial Office, S.W.1.

THE Secretary of State for the Colonies has appointed a committee to advise him on matters relating to the recruitment and training of officers for the agricultural departments of the non-self-governing dependencies. The committee will be constituted as follows: Lord Milner (chairman), Lord Lovat (vice-chairman), Sir Arthur Shipley, Sir Daniel Hall, Prof. J. B. Farmer, Dr. A. W. Hill, Mr. F. B. Smith, Major R. D. Furse, with Mr. P. A. Clutterbuck, of the Colonial Office, as secretary.

A GENERAL discussion on the physical chemistry of igneous rock formation is to be held in the rooms of the Geological Society, Burlington House, London, on Wednesday, October 22, beginning at 3 P.M. The meeting is being organised under the joint auspices of the Faraday Society, the Geological Society, and the Mineralogical Society. A general introduction will be contributed by Dr. J. S. Flett, and papers are expected from Prof. C. H. Desch, Dr. J. W. Evans, Prof. J. W. Gregory, Mr. A. F. Hallimond, Prof. Paul Niggli, Dr. A. Richardson, Dr. A. Scott, Mr. G. W. Tyrrell, and Dr. W. E. S. Turner. Further particulars relating to the meeting may be obtained from Mr. F. S. Spiers, 90 Great Russell Street, London, W.C.1.

THE Educational Number of the *British Medical Journal* (September 6) contains an article by Dr. Andrew Balfour on the teaching of public health, i which he reviews approvingly the provisions of th new regulations for the Diploma of Public Healt introduced by the General Medical Council o January 1 this year. The medical practitioner ca now obtain the Diploma only after he has bee qualified for two years and the period of stud extends over one year. Dr. Balfour also details th provisional scheme of lectures and practical wor of the new London School of Hygiene and Tropic Medicine, of which he is the first Director. Th London School of Tropical Medicine has just bee incorporated in this new School, the buildings f which will be ready in about two years' time and a being built and equipped by the generous gift of tw million dollars by the Rockefeller Foundation. A account of the circumstances of the foundation of th School appeared in NATURE of July 28, 1923, p. 149

Our Astronomical Column.

NEW COMET, 1924 *c*.—A comet of the eighth magnitude, with a tail, was discovered by Mr. Finsler at Bonn on September 15. The following positions have been received, the first two being approximate only :

G.M.T.	R.A.	N. Decl.	Place.
Sept. 15·27	13h 13m 0s	19° 0′	Bonn.
17·27	13 35 0	16 0	Bonn.
19·276	13 52 8	12 7	Babelsberg.

From these the following orbit has been deduced, but as the observations are not exact, it may be considerably in error :

$T = 1924$, Sept. 4·15 G.M.T.
$\omega = 67° 9′$.
$\Omega = 87° 46′$.
$i = 114° 48′$.
$\log q = 9·5940$.

The following positions are calculated from these elements, for Greenwich midnight :

	R.A.	S. Decl.	log *r*.	log Δ.
Sept. 28.	14h 50m 44s	1° 13′	9·8660	0·0801
Oct. 2.	15 7 36	5 33	9·9095	0·1190

SOLAR PHYSICS AT CAMBRIDGE.—The eleventh annual report of the Director of the Solar Physics Observatory at Cambridge, covering the period April 1, 1923–March 31, 1924, has just been published. The bulk of the work accomplished falls under the three headings—stellar work, solar work, meteorological physics. Under the first heading come the very valuable theoretical investigations of Messrs. E. A. Milne and R. H. Fowler, by means of which they have given more precision to the method devised by Prof. M. N. Saha of calculating stellar temperatures and pressures from the degree of ionisation of atoms in the atmospheres of the stars. Furthermore, stellar data, in the light of modern theory, have now been made available for the solution of certain physical problems. On the experimental side, Mr. Baxandall has identified certain absorption bands in the spectra of S-type stars with bands of zirconium oxide—an identification which has since been confirmed by Mr. Merrill at Mount Wilson. The chief solar work of the year, other than routine observations, has been the systematic examination of flocculi by Mr. Butler, and the study, by the Director and Mrs. Beech, of areas and proper motions of sun-spots in the light of the Mount Wilson discovery that the true sun-spot cycle covers a period of 22 instead of 11 years. Mr. Moss has examined the daily records obtained at Kodaikanal of the distribution of prominences at the sun's limb for the years 1904–1922, and has obtained interesting indications of loci on the sun's surface specially favoured by prominence The correlation of the phenomena of sun-spot flocculi, and prominences has thus been the ou standing solar work of the observatory. On th meteorological side, Mr. C. T. R. Wilson has co tinued his investigations of ionising radiations b the "cloud" method, while Dr. E. V. Appleton h been investigating the changes of potential gradie due to very distant lightning discharges, which a regarded as the sources of the disturbances know as "atmospherics" in wireless telegraphy.

RADIATION AND MASSES OF STARS.—Prof. H. Vo describes an investigation into the relation betwee the masses of a number of double stars in th *Zeitschrift für Physik* of August 8; he deals wit 85 double stars from the Lick Observatory Bulleti No. 343, and others which have been considered b Eddington. The masses were calculated from th absolute brightness and the temperature as dete mined from the spectrum, using Eddington's formul and thus the mean ratio between the masses of th brighter and fainter components was determined f different spectral classes (bright component).

The following table shows the result, Mb/Mf bein the ratio of the mass of the bright to that of th faint component, S the spectral class of the brigh component, and n the number of stars considered :

Giants.			Dwarfs.		
S	Mb/Mf	n	S	Mb/Mf	n
M	18·4	2	A	1·6	9
K	2·7	6	F	1·3	23
G	1·9	9	G	1·25	18
F	3·0	5	K	1·23	11
B	4·6	8	M	1·19	2

If one double star is left out from the five F giant Mb/Mf for this class becomes 1·7, and then, with th exception of the B giants, the ratio diminishe towards unity as the state of development of th stars progresses, as would be the case if the mas diminished with the radiation. Assuming that whe a brighter component is in the A (dwarf) class, it mass is 2·5 and the mass ratio Mb/Mf is 1·6, an that both components diminish in proportion t the radiation output, then if Mb has the values give below, in passing through the later spectral classes the values of Mb/Mf are as given in the third lin and may be compared with the values of Mb/M above :

	A	F	G	K	M
Mb . .	2·5	1·5	1·0	0·7	0·4
Mb/Mf .	1·6	1·2	1·10	1·06	1·04

Research Items.

ENGLISH GYPSY BURIAL CUSTOMS.—Mr. T. W. Thompson continues his interesting study of gypsy burial customs in the Journal of the Gypsy Lore Society, Third Series, Vol. III., Pt. 2. Although burials in unconsecrated ground are recorded, the evidence does not on the whole support the view held by some that this was, at one time, the normal practice. In the Heron family, however, only one burial appears in parish registers between 1650 and 1830. The most characteristic funeral rite of the English gypsies was the sacrifice of all the belongings of the deceased which were not buried with the body. The tent and surplus clothes were burnt, possessions which could not be burnt were buried, and the horses and donkeys were sold to gorgios or, in earlier days, were killed. In some cases the living wagon was burnt, even when the deceased was not the owner but only a member of the family, or a child. The reason would appear to be fear that the dead would be restless and jealous at others using their property rather than a dread of pollution, though this may not be entirely absent. In like manner the objects buried with the dead and the offerings made at the grave, though possibly in some degree intended for his service, were primarily to protect the living by making him happy and contented. This dread of the return of the dead is also shown by the avoidance of the names of near relatives no longer living. If another relative or friend bears the same name, a fresh name or nickname is used. Although to swear by a dead relative is the most solemn oath a gypsy can use, a descriptive phrase is substituted for the name. Gypsies also avoid camping places used by the deceased, and, more commonly, abstain by vow or otherwise from his favourite drink, food, or amusement.

IRON WORKING IN THE CAMEROONS.—In *Man* for September, Mr. L. W. G. Malcolm gives an account of iron-working in the Bagam area of the Cameroons. Trades are here under the direct control of the head chief and are specialised, a tradesman being a privileged person and exempt from all work other than his own. Each trade is a guild to which a limited number of apprentices is allocated. No stranger is allowed to enter an iron-smelting hut without a ceremony which includes aspersion of the stranger and the sacrifice and eating by the workers of a fowl purchased by him. The furnace, which is housed in a low hut, differs from the usual West African type in being built in a pit with a sloping approach. It appears to be a development of the Kordofan type, but is much larger. It is square in horizontal section with a back of the natural ground, the sides and front being of clay mixed with chopped grass. The charging hole is on the top between the two sets of bellows, which are arranged on the solid earth at the back, and the gas escape tube. Each bellows has a tuyère, of which the lower end rests on the fire-bed inside the furnace. When the furnace has been lit and charged, which is done gradually, it is kept in full blast by relays of blowers for twenty-four hours. The amount of metal produced at each reduction is about sixty pounds.

THE ANCESTORS OF MAN.—In a popular article contributed by Prof. Henry Fairfield Osborn to the June number of *Asia*, he emphasises his belief that the Tertiary ancestors of man will be discovered in the high plateau region of central Asia. He therefore looks forward with eager anticipation to the results of the new expedition which has been sent by the American Museum of Natural History to collect fossils in Mongolia. Prof. Osborn asserts that "the arboreal theory of man's origin has been given up," and adds that "his ancestors, if tree-living, left their trees in the middle period of the Age of Mammals." He considers that man was driven to live in caves in western Europe by the advance of the ice sheet and the consequent cold conditions during part of the glacial period. It was an episode "of vast importance in the mental and spiritual development of the race, just as the previous period of life in the open was one conducive to its physical and moral development." He thinks that man lived in the open for a comparatively long period, the oldest known race being represented by the flint implements and fireplaces discovered in the Pliocene Crag of Foxhall, Suffolk. Prof. Osborn's article is written to counteract the influence of Mr. W. J. Bryan, who has lately published many attacks on the doctrine of organic evolution, and seems to have a large following in the United States of America.

THE STIFLING OF SILKWORM COCOONS.—In the Bulletin de la Société d'Encouragement pour l'Industrie Nationale for June, M. G. Bertrand describes how extremely sensitive the chrysalides of the silkworm are to the vapour of chloropicrin. The shell in which the chrysalides are naturally enclosed does not protect them appreciably from attack by the vapour, which ensures a complete and rapid stifling of the cocoon. One gram of this agent per 1000 gm. of cocoons acting for one hour at 20° C. will effect the desired result, even if double cocoons are present. On exposure to air, the cocoons lose practically all odour of chloropicrin and dry readily. The stifling produced in this way, which is equal and sometimes even superior to that secured in the usual "dry and humid heat" industrial processes, does not affect the silky envelope, the colour and other original qualities of the cocoons being retained. Neither do the spinning qualities decline. The tenacity and elasticity of the fibres obtained by the new and old processes are found to be the same. The author emphasises the fact that the new method is, both from the academical and industrial points of view, economical, and requires less supervision, since the margin of safety, without fear of damage to the silk, is very considerable. It is claimed that the chloropicrin process is convenient and certain, has no objectionable action on the silk, and requires no complicated or costly installation.

PROTOZOAN PARASITES OF OLIGOCHÆTE WORMS.—The freshwater Oligochætes have long been known to harbour a variety of interesting protozoan parasites. The study of these has lately been taken up by Dr. Doris L. Mackinnon and Miss D. Ines Adam, who contribute two important papers on the subject to the *Quarterly Journal of Microscopical Science* (vol. 68, Part II.). The first of these deals with the life-history of the remarkable genus Triactinomyxon, a genus so complex in its structure and development that it has been doubted whether it is really a Protozoon at all. The peculiar triradiate "spores," with their thread-capsules, so similar to those of the Cœlenterata, are described and figured, and an admirably clear and straightforward account of the life-history is given, with copious illustrations. Most of the known species of the genus occur in the common Thames worm, Tubifex, and the authors' account is based chiefly upon a new species, to which they have given the name *Triactinomyxon legeri*. The second memoir deals with four astomatous Ciliates parasitic in the genera Tubifex, Nais, and Lumbriculus. The authors remark that if a really satisfactory classification of the astomatous Ciliates is ever to be made, it

is necessary that many more of the earliest recorded forms should be re-investigated and re-identified, and their work forms a noteworthy contribution to the subject.

ALKALOIDS FROM DATURA.—The Bulletin of the Imperial Institute (vol. 22, p. 134) contains the results of analyses of *Datura metel*. It appears that if the flowers of this plant are removed during cultivation so that no fruits appear, the yield of alkaloids is increased from 0·24 to 0·36 per cent., the former figure being obtained for normal fruiting plants. Further, the alkaloid present consists almost entirely of scopolamine in deflowered specimens, while in normal plants only about one-fifth of the alkaloid is scopolamine, the remainder being hyoscyamine.

NORTH AMERICAN SPECIES OF ARISTIDA.—Mr. A. S. Hitchcock has described (Contrib. U.S. Nat. Herbarium, 22, 1924, p. 517) the North American needle-grasses of the genus Aristida. These grasses, although widely distributed throughout the world in steppes and prairies, and of considerable economic importance, are only to be distinguished with difficulty and have not always been adequately described. This paper represents a large amount of work and it removes many difficulties. Seven new species are described, together with a number of new combinations.

VARIABILITY IN FUNGI.—Mr. H. R. Briton-Jones records the results of cultural work on *Rhizoctonia Solani* Kühn in the Transactions of the British Mycological Society, vol. 9, p. 200. This fungus is responsible for the "sore-shin" disease of cotton seedlings. A number of forms from Egyptian cotton, from Missouri, U.S.A., India, and also from English peas and potatoes, were examined and induced to produce the fertile stage, *Corticium vagum*, under culture. The various strains remained more or less distinct throughout the experiments, even when allowed to infect a common host plant. They showed; moreover, different physiological properties. Thus the foreign strains, unlike those from Great Britain, were unable to grow at temperatures of 5-8° C. The fungus grows best at the surface of moist, not dry, jellies, just as in Nature it attacks its host plants at the ground level where comparable conditions obtain.

AMERICAN CAMBRIAN GEOLOGY AND PALÆONTOLOGY.—The veteran American palæontologist, Charles Doolittle Walcott, although past the allotted span of life, is, we are glad to see, still ably carrying on the work begun in 1908 of describing the primary fossils of America, and has just brought out Part 9 of vol. iv. of his "Cambrian Geology and Paleontology" (Smithsonian Miscell. Publicat., lxvii.). The present part deals with the Cambrian and Ozarkian Brachiopoda, as well as two new species of Cephalopoda and a new genus, Ozomia, of the family Technophoridæ, formerly considered to be Pelecypods, but now referred to Sars's order Notostraca. The Brachiopoda come principally from Alberta and British Columbia, with a few from various localities in the United States, and a small collection from Novaya Zemlya. These are fully set forth and systematically described, and include fifty new species and a new variety. There are twenty most excellent plates of figures based for the most part on photographs.

MIOCENE FORAMINIFERA.—The mere mention of Foraminifera at once recalls to mind the great triumvirate of Parker, Jones, and Brady, who laid the foundations of our present knowledge of the order, while Jones's pupil, C. Davies Sherborn, compiled a "Bibliography" and an "Index" unsurpassed at the time. Later, the work was carri on by F. Chapman, now in Australia, but the histori graphers in this century of these fascinating but mo puzzling little animals have been Heron-Allen a Earland, whose joint works are familiar and i dispensable to all students. These authors have ju published (Journ. R. Micro. Soc., 1924) an elabora paper on the "Miocene Foraminifera of the 'Filt Quarry,' Hoorabool River, Victoria, Australia which is to be regarded as a supplement to Chapman "Study of the Batesford Limestone," that writ being unable to carry it on further. The materi dealt with consisted of about half a pint of whi organic deposit from the Filter Quarry, which i Foraminiferal contents show must have been la down in a tropical sea at a depth of from 50 to 1 fathoms under conditions very similar to tho existing at the present day round the northe coasts of Australia. A sample from the overlyi marl, taken by Dr. T. S. Hall, indicated that, althou laid down in about the same depth, it must ha been deposited within the continental mud lin Altogether the authors fully describe two hundr and seventy species and varieties, nineteen of whi are held to be new. The new and a few previous named species are amply figured on eight plat containing 118 figures.

KNOLL-REEFS AND THE CRAVEN FAULTS.—In the paper on "The Lower Carboniferous Succession in t Settle District" (Quart. Jour. Geol. Soc., vol. lxx pp. 184-273, 1924), Prof. E. J. Garwood and Mi Edith Goodyear discuss a number of outstandi problems that have hitherto awaited a satisfacto solution. It is shown that the whole of the succe sion north of the North Craven Fault belongs to t North-Western Province, and that in general the Midd Craven Fault may be taken as the southern limit this province. To the south the beds show almo everywhere an abrupt change to the southern type development. Structurally, however, the change complicated by the occurrence between the faults knoll-reefs which belong to the Southern facies, ar by the presence of Yoredale rocks south of the Midd Fault. The knoll-reef limestone of the High Hills of D_3 age and therefore cannot pass laterally into t D_1 limestone against which it abuts on the nort Although there is no other evidence of thrusting, it suggested that the beds have been brought togeth by movement from the fractured southern are against the rigid and undisturbed northern bloc Thrusting seems also to explain the abrupt chan from Southern to North-Western facies. With rega to the origin of the knoll-reef structure, Marr's co tention that limestones of any kind can be folded in knoll-like domes is fully substantiated. It is al shown that the typical knoll-reefs of the souther succession owe their form partly, as suggested b Tiddeman, to the original deposition of rich accum lations of organic remains, and partly to the accentu tion of the quaquaversal structure by subsequer movements.

DISTRIBUTION OF PHILIPPINE EARTHQUAKES.—I the recently issued Bulletin for May 1922 of th Manila Weather Bureau, the Rev. M. Saderra Mas considers the distribution of earthquakes in th neighbourhood of Butuan (northern Mindanao basing his conclusions on the records of six year The average monthly number of earthquakes registere by a Wiechert seismograph at Butuan (1916–1921) i 90. The earthquakes originate in four princip seismic zones. In the first (30-50 km. from Butuan the earthquakes come chiefly from a shallow centr in Butuan Bay. The second and most importan

zone (80-160 km.) includes the whole central and deepest part of the Philippine Deep; the third (270-300 km.) contains the central and southern extension of the Agusan valley (a zone responsible for the great earthquakes of 1893, 1894, and 1911); and the fourth (400-500 km.) the unstable north-east portion of the Celebes Sea. The zone of minimum frequency (0-80 km.) embraces most of the eastern and central Cordilleras, in the latter of which no sensible earthquake, so far as known, has ever originated.

SURVEYS IN SPITSBERGEN.—An article by Mr. J. A. Frazer in the *Geographical Journal* for September gives an account of some explorations carried out by him, in conjunction with Messrs. N. E. Odell and G. Milling and the late Mr. A. C. Irvine, in Central Spitsbergen in August 1923. Their object was to amplify and extend the preliminary survey made in that region in 1921. Landing at Duym Point in Hinlopen Strait, they crossed the island via the Heydenius range and Mount Chernichev to the head of Klaas Billen Bay. The area traversed, which lies to the south of the New Friesland ice-sheet, proves to be a region of complex topography from which the glaciers drain mainly to the east. A provisional map of this small area is published. It is based on photogrammetric work, but it must await the precise positions of the northern beacons of the Russo-Swedish Arc of Meridian surveys before a final version can be prepared. Only the approximate positions of these beacons have so far been published.

DISINTEGRATION OF RADIUM-C.—The September issue of the *Philosophical Magazine* contains an account of the experiments which have been made by Sir Ernest Rutherford and Dr. J. Chadwick to determine the origin and nature of the long range particles which appear from a source of radium-C. They find that the particles of range 9·3 cm. appear in equal amounts in vacuum, helium, oxygen, carbon monoxide and zenon, in whatever way the source is prepared and whether it is covered by a sheet of mica or silica or left uncovered. The paths of the particles as determined by a shadow method and as deflected by a magnetic field lead to the conclusion that the particles are α-particles arising from the disintegration of the radium-C, and are not due to the disintegration of the gas through which the α-particles pass. The same conclusion appears to be probable with regard to the particles of range 1·2 cm., and the two groups probably represent new types of disintegration of radium-C.

THE MEASUREMENT OF FEEBLE RADIOACTIVITY.—A method of measuring weak radioactivity by means of a photographic record of the drift of an electrometer, charged by the ionisation current produced by β- and γ-radiation, is described by Dr. G. Hoffmann in the *Zeitschrift für Physik* of July 12. The ionisation chamber consists of a very open wire cage, the potential of which is kept at 240 volts, and containing an electrode connected to the electrometer. The cage is cleaned with acid and is contained in a brass box, from which the air can be pumped and replaced by carbon dioxide from a steel cylinder. The carbon dioxide, when fresh, contains no emanation. The whole apparatus is surrounded by thick lead cylinders, and the substance to be examined is powdered on a sheet of tinfoil covered with a thin layer of shellac, and placed in a holder round the inner surface of the brass box. All α-rays are absorbed by the carbon dioxide before they reach the cage, and so do not cause rushes of ionisation and irregularities in the photographic record. Among other experiments made with the apparatus, the radioactivity of sodium and cæsium has been studied; taking that of potassium as unity, sodium gives less than 0·002, and cæsium from polluxite, which contains no rubidium, shows no trace of radioactivity.

THE CRYSTALLINE STRUCTURE OF GRAPHITE.—In the *Zeitschrift für Physik* of August 4, Messrs. O. Hassel and H. Mark describe an investigation designed to clear up the discrepancy between the results of Debye and Scherrer and those of Hull; single crystals, natural and artificial, and polycrystalline material were employed, and great care was taken to avoid distorting the soft material, which, when in the form of powder, was not pressed into rods, but fastened with collodium to a thin wool thread, stretched in the axis of the camera. Different characteristic X-radiations were employed, and the rotation diagram method, the Laue method, Bragg's reflection method, and the Debye-Scherrer method were all made use of, the intensity relations of the reflections being determined. Consideration of the whole of the diagrams in detail showed that, if all the carbon atoms have the same valency, there is no space group which gives the observed interferences. It is necessary to assume a *c*-edge-centred lattice, with particles having the reflecting power R_1, shifted a certain amount with respect to a lattice with reflecting power R_2 and with the particles in the positions for closest packing; the smallest possible orthohexagonal cell measures $a = 2{\cdot}47$ Å, $b = 4{\cdot}25$ Å, $c = 6{\cdot}70$ Å, and contains eight atoms; a figure in the original paper shows the relations between the particles. The measurements of Ewald, Debye, Scherrer, and Hull agree with the structure determined.

GLASS TECHNOLOGY.—The Experimental Researches and Reports published by the Department of Glass Technology of Sheffield contains in volume 6, 1923, among other papers, one on natural sillimanite as a refractory material, by S. English, and one on heat-resisting glasses by Prof. Turner. The first paper gives an account of some trials of natural sillimanite, which melts at 1816°, in place of clay as a refractory. Mixtures with clay were used. The mixture with 9 per cent. of clay showed a very small shrinkage on drying, and on burning at 1400° the further contraction was negligible. The porosity was rather less than standard pot clay, and the action of molten glass was much less than that on clay. Prof. Turner's paper gives an interesting account of the developments in the manufacture of heat-resisting glasses, beginning with the systematic work of Schott at Jena in 1892, and including "Pyrex" glass containing 80·62 per cent. of silica, 11·9 of boric anhydride, 2 per cent. of alumina, 3·83 per cent. of soda, and small quantities of other constituents. In America, tea and coffee pots, tea-cups, and cooking ware are made from refractory glass.

SODIUM TUNGSTATES.—We have received a reprint of a paper on sodium tungstates by Dr. E. F. Smith, published as a contribution from the John Harrison Laboratory of Chemistry, University of Pennsylvania. The sodium tungstates described in the literature were re-examined, and the conditions for preparing 5:12 sodium tungstate determined. With normal sodium tungstate (1:1) and meta-sodium tungstate (1:4) as opposites in basic and acid character, the intermediates 3:7, 5:12, and 4:10 were found as products of their union. The 1:2 and 1:3 salts do not exist, probably because of their very ready hydrolysis. The suggestion that paratungstates exist in two modifications, namely, 3:7 and 5:12, was not confirmed. Carbon tetrachloride as a new reagent was extensively employed.

The Japanese Earthquake of 1923.

SOON after the earthquake of September 1, 1923, the Imperial Earthquake Investigation Committee appointed a number of sub-committees to investigate the earthquake from different points of view, dealing with observations on seismology, geology, hydrography, and geodesy, and, on the practical side, with problems of architecture and civil engineering. The complete reports of the various sub-committees will, it is expected, be published before many months are over. In the meantime, Prof. A. Imamura, who has succeeded Prof. Omori as the head of the Investigation Committee, has written a valuable report which appears in No. 6 of the "Seismological Notes" of the Committee.

As Prof. Imamura points out, the earthquake was by no means the most severe that has visited the Japanese Empire—it was inferior, for example, to the Tokyo earthquake of 1855—though, in the destruction of life and property, it is probably without a rival. After five minutes, the motion had so far subsided that Prof. Imamura was able to visit the observatory of the Seismological Institute. Here he found that nearly all the instruments were wrecked. Only one component of one seismograph kept working all through the earthquake, but, within five minutes, four seismographs (recording actual size or up to twice that size) were readjusted or repaired, other more sensitive instruments being added after a day or two. These repairs were impeded by the outbreak of fire in the University, and it was not until 10 P.M.—the earthquake occurred just before noon—that the Institute and its observatory could be regarded as safe. The office of the Investigation Committee was burnt with its important papers.

From the direction and duration of the preliminary tremors, it is estimated that the epicentre was 92 km. from Tokyo in the direction S. 26° W., that is, under Sagami Bay, in lat. 34° 58·6′ N., long. 139° 21·8′ E. The angle of emergence at Tokyo was 10°, giving a depth of about 15 km. for the focus. The curve representing the relation between the focal distance and the time of transit of the first tremors is practically a straight line, from which it is found that the time at the origin was 11 h. 58 m. 32 s., and the velocity of the first tremors 7·5 km. per sec. for the neighbourhood of the epicentre. The total duration of the record of the great shock was 2 h. 20 m.

From the initial direction of the movement at different places within a radius of 170 km., Prof. Imamura concludes that "the seismic action might have been applied in such a manner that the compression along a deep stratum was directed towards the north and west."

The greater part of the coast of Sagami and Tokyo Bays was elevated, the maximum amount of uplift being a little more than 2 metres. Such changes are slight compared with the displacements in the bed of Sagami Bay. The total area of depression is estimated at 700 sq. km. and that of elevation at 240 sq. km., the total volume depressed at 50 c. km., and the volume elevated at 20 c. km. This implies that the average depression was 39 fathoms and the average elevation 45 fathoms.

The tsunami, or seismic sea-waves, were greatest along the shores of Sagami Bay, where they reached a height of 8 metres at Ito and Aziro, 9 metres at Ainohama, and 12 metres at Atami. From the directions in which the sea-waves advanced, it follows that the most prominent waves came from neighbouring areas of elevation. The enormous depressions gave rise to only minor waves.

The cause of the earthquake is still unknown. Possibly there may have been a great fault-movement in the heart of Sagami Bay, but so far no trace of has been discovered. On land, two minor faults ha been observed, one near Nagasawa in the Miu peninsula, the other near Nago in the Bo-so peninsul Both are about 2 km. in length, and have a maximu vertical displacement of one metre.

Four slight shocks, with epicentres in or ne Sagami Bay, were registered at Tokyo during th preceding month, the last one eight days befo the earthquake. Otherwise, the great shock ca suddenly and without warning. The study of th after-shocks is complicated by the great size of th focal area, and by the occurrence of another destru tive earthquake, belonging to the same zone, and nearly equal strength, at 2 h. 47 m. on September the after-shocks of which mingled with those of th first earthquake. The after-shocks originated three areas, the first including the Bay and Provin of Sagami, the second the Bo-so peninsula and se bed to the east, and the third the drainage-area the River Tone to the north of Tokyo. Of the 12 after-shocks recorded at Tokyo during Septembe 46 (including the majority of the strong after-shock occurred in the first zone, 71 in the second, and 25 the third, while the epicentres of more than a thousan (nearly all slight and none strong) are unknown.

The latest statistics show that the total numb of lives lost was 99,331 (59,065 in Tokyo and 23,44 in Yokohama), 103,733 were wounded, and 43,47 missing. The number of houses completely collapse was 128,266, while 126,233 half collapsed, 447,128 we burnt, and 868 washed away. A second table giv the number of houses collapsed in the places mo severely damaged, and the percentage of such wit regard to the number of pre-existing houses. Yokohama the percentage was as low as 12·4, b in Kamakura it rose to 84·4, and in six plac it exceeded 90. In one of these (Simosoga) was 97·8.

A recent issue of the Bulletin of the Seismologic Society of America (vol. 13, 1923, pp. 124-14 contains an interesting article on the Japane earthquake by Dr. T. A. Jaggar, the well-know vulcanologist and founder of the Volcano Observato on Hawaii. Dr. Jaggar spent October in th meizoseismal area, and he has added many details t our knowledge of the earthquake. He estimates th value of property destroyed at between four and fi thousand million dollars, and states that some wel informed Japanese put the loss of life at about fo hundred thousand. The volcano of Oshima showe no unusual phenomena at the time of the earthquak Dr. Jaggar describes the changes of level of the flo of Sagami Bay and along the coast-line. These a summarised above and in NATURE, vol. 113, pp. 47 474. He considers that the belt of maximum d pression was the epicentral tract. "As the shorelin belts all about were lifted or lowered only one t eight feet, the depression mechanism was of a differe order from the margin mechanism. It appears t have been a collapse of blocks into a pit or rift in th bottom of the bay aligned with the island volcan chain, which extends hundreds of miles south-sout east." The after-shocks were of two kinds, th slow prolonged type (resembling the first shock) an the abrupt short type preceded by a booming nois Dr. Jaggar quotes at length the accounts of severa careful observers in Tokyo, Yokohama, etc. Wit regard to the place of the earthquake among othe great shocks, he concludes that it was not mor intense than the Mino-Owari (Japan) earthquake c 1891, and probably much weaker than the Yakuta Bay (Alaska) earthquakes of 1899. C. D.

Standardisation of Scientific Glassware.

THE Joint Committee for the Standardisation of Scientific Glassware, which was promoted by the Institute of Chemistry (30 Russell Square, W.C.1), and includes thirty-seven members representing mainly users and manufacturers, has published its first report, entitled "Units of Volume," in which is recorded the unanimous recommendation to discard the cubic centimetre as the standard unit for scientific glassware and to institute therefor the litre and the millilitre. Since, however, some chemists still prefer to use the Mohr unit, the Committee has added two further recommendations to obviate confusion between the two systems, although it hopes that in time the litre and the millilitre will be adopted exclusively. Vessels graduated on the Mohr system, it is recommended, should be marked "G.W.A." (grammes of water in air), and the numerical relation between the units will be 1000 G.W.A. = 1002 ml. The National Physical Laboratory will test vessels of both kinds, and those graduated on the Mohr system will be marked differently from the others.

Whereas the volume of a body of simple geometrical form is readily calculated from its linear dimensions, the volume of a hollow vessel designed to hold a fluid is determined more easily and more accurately by finding the weight of water required to fill it. But the use of two distinct types of units has many disadvantages, especially if there is no simple numerical relation between them. To establish such a relation, the originators of the metric system defined the kilogram as the mass of water which occupies one cubic decimetre at its temperature of maximum density; so that the unit of volume, the litre, could be defined either as a cubic decimetre or as the space occupied by a kilogram of water at the specified temperature. A cubic decimetre of water was, however, not a practical standard weight, and the kilogram was therefore re-defined as the mass of a particular standard weight (*kilogramme des Archives*). In accordance with this change, the litre was re-defined as the volume occupied by one kilogram of pure water at its temperature of maximum density and under normal atmospheric pressure. Thus the litre became independent of the metric unit of length, and the cubic centimetre lost its relation to the volume of a mass of water. The precise relation between the litre and the cubic centimetre was found experimentally to be 1 litre = 1000·027 c.c. ±0·001), a difference so small as to be negligible for ordinary volumetric glassware.

The introduction of the Mohr system caused confusion, inasmuch as by it the unit volume was defined in terms of the apparent weight in air of a mass of water at room temperature. By this system a "litre" flask contains 1000 gm. of water (weighed in air against brass weights) at 17·5° C., which is the equivalent of 1002 c.c. as defined above; but the followers of Mohr designated the volume occupied by the 1000 gm. of water one litre, and the thousandth part of it one cubic centimetre. The exact relation between the Mohr unit and the millilitre is given by the fact that the amount of water which weighs 1000 gm. in air of density 0·0012 gm./ml., when weighed against brass weights of density 8·4 gm./ml., occupies a volume of 1002·021 ml. at 60° F. The difference between this figure and 1002, namely, 2 parts in 100,000, is negligible in practice, and hence the Committee recommends the adoption of the round number, thus facilitating inter-conversion of "G.W.A." and millilitres.

The Committee has also considered the accuracy of volumetric glassware, and recommends the adoption of only two grades, namely, Class A, or Standard Apparatus, which must pass the N.P.L. or other approved test, and the Class B, or Commercial Grade Apparatus, of cheaper quality and for general use, which must, however, be guaranteed by the manufacturer to comply with certain minimum requirements. The Class A Tests and the Class B Tests of the National Physical Laboratory (as revised in a recent pamphlet to be obtained from The Director, N.P.L., Teddington, Middlesex) are approved, and confidence is expressed that manufacturers will be able to supply guaranteed Class B apparatus at reasonable prices. Finally, the Committee urges strongly that volumetric glassware should never be ordered without specifying the limits of accuracy required.

Cod and Cod Fishery.

THE three papers included in No. 7, vol. vi., series ii., Fishery Investigations, Ministry of Agriculture and Fisheries (H.M.S.O., price 3*s*.), record an investigation undertaken as part of the general programme of research on the cod which was initiated by the International Council for the Exploration of the Sea in 1921.

The first, under the initials of Mr. W. C. Smith, deals with the Irish Sea cod fishery. This fishery is of importance only during the winter months, and it is carried on chiefly by Manx long-line fishermen and a few Fleetwood steam-liners. With the approach of winter and the decreasing temperature of the water, large mature cod move into the Irish Sea from the north to spawn. The return movement begins in April and is usually completed by the end of that month. Spawning takes place during February, March, and April in the waters around the Isle of Man and off the Cumberland coast. The young immature fish remain in these waters throughout the year.

The second paper, by Prof. Jas. Johnstone, gives an account of the cod as a food fish. It contains a summary of most of the results of analyses of cod and cod products, which may be found in König's big volume and in the work by Atwater. The results obtained from Irish Sea cod are also included. The results show that the cod is a "fat-poor" fish. Less than about half of the total weight of the entire fish is edible. In the edible substance, about 81 per cent. to 84 per cent. is water, and there is practically no fat; about 1 per cent. is ash, and the rest (about 14 to 17 per cent.) is protein.

The third paper, by Prof. Johnstone and Mr. A. Scott, summarises information on the parasites and diseases of the cod. Ectoparasites and endoparasites are set out under orders and families, and a note on the occurrence of each is given. Both are less numerous in the cod than in many other species of fishes. The whiting and haddock, for example, are much more affected than is the cod. Cases of sarcomatous and other tumours, lupus and ulceration of the body, "columnar disease" in the muscle, diseased liver, stone in the urinary bladder, and ovarian degeneration are on record. Humpbacked cod in which the head is fairly normal in shape, while the trunk and tail regions are shortened and the backbone is thrown into a gently spiral form, are occasionally seen. One-eyed cod suggestive of irregular development rather than of injury are also recorded. References to literature on hermaphroditism are given in the concluding section of this instructive paper.

University and Educational Intelligence.

ABERDEEN.—Prof. Alex. Findlay has accepted an invitation to visit Stanford University, California, as acting-professor of chemistry for the three-quarters of the academic year, January to August, 1925.

LEEDS.—The University and the Philosophical and Literary Society have arranged a joint programme of lectures and music for the autumn term. The lectures include one by Prof. L. Bairstow on some aspects of modern aerodynamics, one by Mr. J. S. Huxley on recent progress in developmental physiology, and three by Prof. A. Gilligan on the geology of Yorkshire, all of which are free. Prof. S. Brodetsky and Mr. S. Stoneley are giving a popular course of six lectures on astronomy and Prof. P. F. Kendall three lectures on man and the ice age.

LONDON.—The two following courses of free public lectures at King's College are announced:—On Wednesday, October 8, and seven successive Wednesdays, at 4.30, "The Histology of the Nervous System," by Dr. C. da Fano; on Wednesday, October 8, and four following Wednesdays, at 5.30, "The Human Body and its Function," by Prof. R. J. S. McDowall.

On Friday, October 3, at 5.30 P.M., Prof. T. Percy Nunn will deliver a free public lecture at University College on "The Scientific Interpretation of Nature." This lecture is introductory to the new course for the M.Sc. on the principles, history, and method of science.

APPLICATIONS are invited for the headship of the chemistry department of the Borough Polytechnic Institute. Particulars and a form of application are to be obtained from the principal of the Institute, Borough Road, S.E.1.

IT is stated in the *Times* that schools of forestry are to be established at the University Colleges of Auckland and Canterbury by the New Zealand Government, which will make a grant of 1000*l.* a year, with an additional 600*l.* towards the cost of initial equipment.

INDIAN education in 1922–23 is reviewed by the Educational Commissioner with the Government of India in a report recently published at Calcutta. Commenting on the reorganisation of the University of Allahabad, the report states that some dissatisfaction has been expressed with the arrangement by which a residential teaching university is combined with affiliated colleges, some of which are situated at places very far distant from the university centre. This has led to movements for the establishment of universities at Agra and in Rajputana.

WE have received a "London University Guide and University Correspondence College Calendar, 1924–25," issued by University Correspondence College, Burlington House, Cambridge. This is a handy little volume of 200 pages, giving in convenient form regulations, syllabuses, and advice as to appropriate text-books for preparation for the matriculation and external degree examinations of the University of London. It is issued gratis. It was formerly published annually, but its issue has been suspended since 1915.

THE London County Council recently opened an education publicity campaign by issuing an excellent little pamphlet entitled "The Londoner's Education." This has now been followed by a sixpenny "Guide to Continued Education in London," this being No. of a "Privileges of Citizenship" series. In additi to giving a concise account of the provision ma for continuation education of all types—commerci technical, trade, domestic, literary—and of t facilities available for all classes of students f improving their knowledge and using profitab their leisure hours, the booklet gives lists of numero pamphlets, obtainable, most of them gratuitousl at the Council's offices, which contain more detail information. It gives also a convenient list several hundreds of institutions offering eveni classes.

THE Ministry of Agriculture and Fisheries and t Board of Agriculture for Scotland are inviti applications for a limited number of agricultur scholarships, of a maximum annual value of 200 which are open to students proposing to take up pos as agricultural organisers, teachers or lecturers agriculture, etc. Candidates should usually graduates of a university. The scholarships a tenable for two years, and are intended to gi students an opportunity of broadening their kno ledge of agriculture both at home and abroad. The value will vary according to the scholars' means, a to the cost of living prevailing in the country visite laboratory fees and travelling expenses will be d frayed. Particulars may be obtained from t Secretary, Ministry of Agriculture and Fisheri 10 Whitehall Place, London, S.W.1, in the case English and Welsh students, and from the Secretar Board of Agriculture for Scotland, York Buildin Queen Street, Edinburgh, in the case of Scotti students. The latest date for receiving applicatio is October 31.

THE Industrial Fellowship scheme of the Mell Institute of the University of Pittsburgh has been operation for thirteen years. A recent report of t director shows that at the close of the year 1923– no fewer than 83 research chemists and engineers we employed at the Institute, and that the sum 412,132 dollars had been contributed for sustaining th work by the industrial fellowship donors. The tot amount of money given by industrial firms to t Institute since 1911 is 2,719,103 dollars. The histo and research system of this unique institution are d scribed in an illustrated booklet, which also contai one of the forms of agreement under which fellowsh foundations are accepted. The salient features the system are as follows: A firm or an associati of manufacturers having a problem or group problems that needs investigation, provides a sum money (about 5000 dollars for each investigator to employed for a whole year) sufficient to cover salari of investigators, operating charges, and purchase necessary equipment; the Institute selects the fell or fellows, and furnishes laboratory, library, co sultative facilities, the use of its permanent resear equipment, direction to the progress of the work, a an environment that stimulates productive investig tion; all results are the property of the donor, whom in the meanwhile monthly progress reports a regularly submitted. Although primarily an i dustrial experiment station, the Institute recognis the need of fundamental scientific research as a bac ground and source of stimulus for industrial researc and has funds which are devoted to the prosecution investigations not suggested by industry but plann by the permanent staff, four of whom were engag in purely scientific research of this type during t year. Co-operation between the fellows is stimulat by a social club, in the activities of which all a expected to take part.

Early Science at the Royal Society.

September 27, 1662. The president communicated ...tter sent by his majesty to the duke of Ormonde, ...-lieutenant of Ireland, recommending the Royal ...ety for a liberal contribution from the adventurers ... officers of Ireland for the better encouragement ...he said society in their designs. Whereupon it ... ordered that a copy of the said letter should be ...n; and the humble thanks of the society be ...rned to his majesty by Sir Robert Moray, for ...th great testimony of his royal favour.—The presi... was desired to return likewise the thanks of the ...ety to Mr. Secretary Nicholas and Mr. Williamson, ...their readiness to assist the society in the king's ...ers to Ireland without taking fees.

September 28, 1664. There was read a letter of ... Wallis to Mr. Oldenburg, giving an account of his ...ing performed the task imposed upon him con...ing Mr. Horrox's astronomical papers, by com...ing the copies with the originals, and digesting all ...several pieces into one body, and prefixing to it ...epistle addressed to the president of the Society.—... secretary informed the Society that at Rome ...ervations of Jupiter had lately been made with ...new glasses of Campani, by means of which, six ...ts had been discovered in that planet, four of ...ich had appeared more obscure, and two more ...ir than the rest of his body.—The secretary ...ing also formerly written to his correspondents in ...nce, to inquire into the truth of the odd experi...nt delivered by the jesuit Casati, in his book, ...ituled, "Terra machinis motu," and received an ...wer thereto by a person who had consulted the ...hor of the book himself concerning the same, he ...nmunicated it to the Society; the substance of ...ich was that the said Casati had not tried the ...periment himself, but had seen it tried by a ...ntleman, named Don Innocenzo Conti, viz., that the ...uor extracted out of a certain bismutum, and well ...tified, when sealed up hermetically, and exposed ...the moon, rose in the full, and fell in the new moon.

September 30, 1663. Mr. Palmer presented the Society, ...m Mr. Edward Diggs [Digges] with two sorts of silk, ...e coarse, the other fine, sent from Virginia, and ...ade there; together with some written observations ...Mr. Diggs' concerning silk-worms, and the making ...silk, contrary to the received opinion thereof. Mr. ...lmer was desired to return the Society's thanks to ...e presenter, and to let him know, how much they ...re pleased with his care and concern for improving ...this manufacture; and how glad they should be to ...ceive information, from time to time of the progress ...it. Mr. Hill was desired to get the parcel of the ...arser silk to be put into a stuff for a cover for the mace.

1674. Mr. Hooke reported, that upon his making ...e proposal of the council to Mons. Papin of twenty ...unds a year certain for writing all letters for the ...ciety, he had accepted the same.

October 1, 1662. Dr. Wren presented some cuts ...ne by himself in a new way of etching; whereby, he ...id, he could almost as soon do a piece on a plate of ...lass, as another should draw it with a crayon on ...per.—Dr. Merret read his paper concerning the ...anting and preserving of timber; together with his ...llection of those statutes, that have been formerly ...ade by the parliament of England.

October 3, 1666. The lord bishop of Exeter being ...quested to communicate the observations of ...piter's satellites made by Mr. Laurence Rooke in ...der to the calculating of tables of their motion, his ...rdship desired, that he might be put in mind of it ...Mr. Hooke, and that he would purposely come to ...s library in Gresham College to look them out.

Societies and Academies.

LONDON.

The Institute of Metals (Autumn Meeting), September 9.—R. J. **Anderson** and E. G. **Fahlman**: A method for measuring internal stress in brass tubes. The method for measuring longitudinal internal stress is called the strip method, and is carried out by slitting a narrow strip longitudinally in a piece of tubing; for example, a strip 2·75 inches long and 0·10 inch wide in a 3·25 inch tube length; and then releasing one end of such a slit strip by cutting. Stress is indicated by the springing out of the freed end, and can be calculated from the modulus of elasticity of the material and the distance in movement of the freed end.—D. H. **Andrews** and J. **Johnston**: The application of the ideal solubility curve to the interpretation of equilibrium diagrams in metal systems. The method of plotting here discussed has not been applied previously to metal systems. In many systems the simple theory fits the observations better than had been anticipated, and may at least be used as a guide in criticising and simplifying experimental work.—Guy D. **Bengough** and R. **May**: Seventh report to the corrosion research committee of the Institute of Metals. The problem of corrosion is considered largely from the point of view of the "scale" of corrosion products which forms on the surfaces of such metals as copper, zinc, and brass immersed in sea-water. A large proportion of tube failures in modern condensers is due to local impingement of aerated sea-water; the rapid corrosion is due to the local removal of protective scale by the impinging stream. Certain types of preformed scales may be very resistant to this type of action. The occurrence of "dezincification" is due, not to bad mixing of copper and zinc in the manufacture of brass, but to the absence of arsenic from tubes. The electrolytic method of protection of condenser tubes generally gives negative results, but occasionally good results have been reported; these seem to be due to chance secondary effects particularly of the anode products. Corrosion of brass may be due to metal-ion concentration cells or oxygen-distribution cells. With high-speed water streams the metal-ion concentration cell may become the more powerful and render the metal anodic and severely corroded; deposits of sand, porous masses of corrosion products, etc., may cause oxygen distribution cells to become active and set up local corrosion, but the most rapid cases of corrosion seem to belong mainly to the former type. Sometimes the two types of action reinforce one another.—E. H. **Dix**, Jr., and A. J. **Lyon**: Comparative results on copper-silicon-aluminium and other aluminium alloys as obtained on separately cast specimens and specimens cut from a crankcase casting. Copper-silicon-aluminium alloy is particularly well adapted for complicated castings which do not require a large amount of machining. The casting properties of Alpax are similar, but it has a very low proportional limit and is inferior in this respect. Lynite 195 has uniform and desirable physical properties. The proportional limit is considerably above any of the alloys tested. The foundry practice, however, is more difficult for this type of an alloy. 8 per cent. copper-aluminium alloy is suitable for the general run of castings and can be cast in sections $\frac{3}{16}$ in. or more in thickness without much difficulty.—R. **Genders**: The extrusion of brass rod by the inverted process. Precautions are necessary to secure good surface, the method adopted for the present being the avoidance of entrance of the skin of the billet into the region of flow. The structure of the extruded rod does not show the concentric zones of

material varying in crystal size and physical properties often produced by the peculiar nature of the flow which obtains in the ordinary process. The rear portion of the rod is variable in structure and hardness from centre to outside, but in a continuous gradient. All possibility of "core" defect is excluded, and, if defects are allowed to arise, they will be visible on the surface of the rod.—D. **Hanson** and Grace W. **Ford**: Investigation of the effects of impurities on copper. Part II.—The effect of iron on copper. Solid copper will dissolve about 4 per cent. of iron at 1100° C., but the solubility at lower temperatures is much less. Within the limits of solid solubility, the electrical resistivity increases rapidly as the iron content is raised: hence iron is extremely deleterious in copper for electrical purposes. The tensile strength is raised by 2 per cent. of iron from 14·5 tons per sq. in. to about 20 tons per sq. in. The effect of heat-treatment is relatively small. Iron has no great embrittling effect.—Sir Thomas K. **Rose** and J. H. **Watson**: Experiments on the working of nickel for coinage. The experiments were made in order to determine the conditions in which nickel for coinage could be cold-rolled in the existing rolls at the Royal Mint. It was found impossible to prepare coins containing 99 per cent. nickel with 1 per cent. of manganese, magnesium, carbon, iron, silicon, etc., such as are manufactured with the aid of hot-rolling. By the addition of 2 per cent. manganese, however, castings can be prepared suitable for cold-rolling and conversion into coin. The coins consist of a solid solution, and accordingly resist tarnishing and corrosion equally well with those containing 99 per cent. or more of nickel, such as are in circulation abroad.

Psychologists and Examiners.[1]

THE idea is prevalent in Great Britain that no government department will accept a new thing until it has become hoary with age. The Consultative Committee of the Board of Education has disproved the generality of the truth of this idea by the acceptance of a view which dates from the present century, and it has at the same time proved its common sense by refusing to endorse a proposition which is held true by the experts who are in a position to decide, but is not sufficiently established for non-experts to be convinced of the truth of it.

The thing the Consultative Committee accepts is the value of intelligence tests for use at the beginning of each stage of school education for the purpose of sorting out the children fit to profit by further education from those who are not fit. Such tests were used last century for ascertaining mental deficiency, but their use for the normal child first became a possibility twenty years ago when Prof. Spearman showed how numerical measures could be obtained by means of the coefficient of correlation. The approval of the Consultative Committee will lead to the rapid extension of the use of these valuable tests, which hitherto have been applied only sporadically in Great Britain.

The proposition which the Committee refuses to endorse is that there is a "general ability" which takes part in the various activities of the mind, and usually takes an important part. The use of numerical measures for psychological quantities soon brought Spearman to realise the existence of this general ability, and his writings on the subject are conclusive to readers who understand the calculation of a correlation. For the Committee to accept this proposition would have meant simply that it accepted the dictum of the experts and that it was not its own conclusion. Such acceptance is impossible for a committee the opinion of which is to carry weight, and the refusal to endorse the proposition is evidence that any conclusions it does accept are its own and thus gives these conclusions increased weight. We do not, of course, mean that the members of the Committee are not experts; we mean that although they are all experts in education, they have not the particular expertness wanted for this question. The attitude towards intelligence tests shown by men with no special knowledge even of education was exemplified by the House of Commons when that body, so wise in ordinary matters, imagined that it had finally disposed of intelligence tests by the invention of the term "jazz papers" amid Rabelaisian laughter; and by the Southborough Committee, which

[1] Report of the Consultative Committee of the Board of Education on Psychological Tests of Educable Capacity and their Possible Use in the Public System of Education. Pp. xii+248. (London: H.M. Stationery Office, 1924.) 2s. net.

also condemns them and adopts the scornful House of Commons term.

If we wish to estimate the value of any method of testing, we must first be clear about the object for which the test is to be used. The object the Consultative Committee has mainly in view is the testing of educable capacity, that is to say, the discrimination between children fit to undergo a further stage of education and those unfit to do so; and the discussion of this problem is sound. The Committee is, however, strangely blind to other purposes for which examinations may be held. Thus, for example, it looks on the First and Second School Examinations as the end of all things rather than as a test of fitness for a career or for admission to a university.

The tests that came under the consideration of the Committee may be classified as follows :

1. Tests of inborn qualities such as (*a*) general ability; (*b*) special ability, including aptitudes for particular vocations; (*c*) personality, including temperament and will.

2. Attainment tests which gauge the degree to which the examinee has benefited by his education.

3. Physical qualities which, if their investigation is found worth pursuing, will be found to subdivide into inborn qualities and acquired qualities.

These tests fall to be considered for their value for (1) entrance to an educational stage, (2) entrance to life work.

Of the tests we have enumerated, the Committee deals rapidly with all but the tests of general ability. It considers that tests of special ability and of personality may possibly have value, but that much development is necessary before it can recommend them for general use.

The approval by the Consultative Committee of the use of psychological tests of general ability is given on the understanding that :—(1) The object is to test educable capacity. (2) Elements of personality, such as temperament and will, must also be taken into account. (3) The possibility is to be kept in mind that a particular temperament or kind of will may upset the results and vitiate them as a measure of educable capacity. (4) The psychological tests now in use bring out results too high in the case of the verbalist (who is especially skilled in language), and too low in the case of the non-verbalist, in whose case justice requires the application of other tests such as performance tests. (5) The questions must be framed with proper regard to the child's environment, so that, for example, urban questions must not be set to the rural child.

It is well for us to consider what guidance we can find in the report for other purposes, as, for example, for School Leaving Examinations and First School Examinations, and for examinations used by a business firm to choose its employees. For the business in the answer is clear. In addition to a reasonable of general knowledge and a suitable personality candidate must possess an appropriate grade of ge intelligence. The older fashioned examination and often does, test intelligence incidentally, but it not discriminate between intelligence and other ties and determine the degree of intelligence a cand possesses. The psychological test does so, and is on account valuable to the business firm.

The School Leaving Examination appears in main to be an attainment test held for the purpo ascertaining what the school has done for the pupil this is its object, the psychological test seems to ha place in it. Indeed, so far as the examination ha object of measuring the diligence which the boy o has shown, it might even be held that general in gence should be discounted on the ground that b help the cleverer pupil of little diligence makes as a show as the less clever but very diligent pupil. O other hand, so far as a school examination serv a university entrance examination, it should re such intelligence as is necessary to undertake st of a university grade.

It is clear, then, that the value of the psycholo test for a School Leaving Examination can be de only after the true object of the examination has determined. The question of the true object sh accordingly be among the first references to the committee, the appointment of which is recomme by the report before us.

The value of the psychologist in intelligence te proved. In attainment tests, that is, in the tes knowledge such as are conducted by the older exami bodies, there is need for co-operation between psychologist and the old-fashioned examiner. schemes of these examinations must be worked ov see whether the psychologist can improve them. give an example, the old examiner, when he found the examination results from two subjects ranged candidates in very much the same order of m argued from this fact the excellence of the two ques papers ; the psychologist offers an alternative expl tion, namely, that the two tests measure much the s qualities ; and this explanation must lead us to sider whether it would not therefore be sufficien employ one of the question papers and drop the ot

On the other hand, the psychologist must remen that the region of attainment tests is not virgin The old-fashioned examining bodies have been at w for long periods, and, although equipped only common sense in place of psychological knowle have attained conclusions which may require s adjustment but are likely to remain valid.

ne idea that requires discussion between the old aminer and the psychologist is that of the "short swer," usually consisting of a single word. The idea of he "short answer" seems to have been transferred, thout much consideration, from the intelligence test to he attainment test, and it is for the psychologist to nish evidence as to the circumstances in which a stion paper framed on these lines is better than the stion paper usual in Great Britain, in which a candie has three hours to answer half-a-dozen questions, l better than the customary French examination per in which three hours are devoted to a single stion.

The use of the competitive interview is quite recent l the experience of it slight. It has not yet had time be standardised. It is a problem on which the old aminer and the psychologist ought to co-operate, the dible point of view being even more valuable here n in long-established tests.

FEW of us consider that we occupy the exalted positions which Nature or a benevolent Providence intended us to fill, and none, except perhaps the uly meek, hesitates to use legitimate agencies for rthering his advancement. Scientific workers are exception to this rule, and of late they have been veloping a "class consciousness," and organising emselves into associations that correspond in certain atures to the trades unions of the proletariat. lthough they have their differences of opinion, those ho depend upon science for their daily bread are nanimous in thinking that their position in the social ale is unduly low and incompatible with the value their work for the community. The worker in pure nd applied chemistry does not lag behind the rest. His picturesque forerunner, the astute alchemist, layed on the whole an ignoble part in administering the acquisitiveness of kings and courtiers; and the odern industrial chemist keeps up the tradition by selling his services to employers whose main ambition is to transmute materials and labour into gold: he seldom occupies a commanding position either in the industrial or the social world.

It may, however, now be said that chemists have passed through the first stage in their social evolution, inasmuch as they are fully cognisant of their unmerited inferior status. They have entered upon the second stage, which is combination for a common purpose; but they have yet to negotiate the difficult final stages, which comprise the selection of competent leaders and the conversion of their fellow-citizens. The chemical world has never been rich in men possessing the human qualities needed for effective leadership, and the task of selection is by no means easy; for the chemist is not only by nature an individualist, he is also a born rationalist, neither exhibiting emotion nor being influenced readily by it.

To convince the man in the street of the vital importance of chemistry, and inferentially of the vital importance of the chemist, is also difficult, as the means available for this purpose are limited. Chemistry, like most of the other sciences, is taboo to the editor of the popular newspaper and to the popular author; actors, preachers, politicians, prominent soldiers and sailors fight shy of it (though some of them may accept seats on the boards of chemical companies). It was, therefore, a good idea that prompted the Association of British Chemical Manufacturers and the Society of Chemical Industry to bring out a series of popular prints on chemical topics in connexion with the British Empire Exhibition, and all chemists will bless them if the seed they are sowing falls on fertile soil. The success of such propaganda must, obviously, depend not only on the nature of the material selected, but also on the manner in which it is treated; and this consideration impels one to comment on popular scientific literature in general.

Comparisons are sometimes drawn between the good old days when Huxley and Tyndall drew large audiences of working men and others to their popular lectures and wrote essays that were widely read, and the present time when the demand for such work is very poor. With all respect, nay, veneration, for these great expositors, it is doubtful if they would achieve to-day the same success that they won thirty to fifty years ago. The world has become more material and sensation-loving, so that a new method of attack seems imperative. A successful popular writer of to-day must understand the psychology of his readers and adapt his style to the nature of his audience. Now this is not an easy proposition, particularly for the writer of science, because, from the point of view of scientific knowledge, the man in the street is not one abstract individual but

several. For the present purpose, he may be conceived either as a man who is totally ignorant of and completely indifferent to science, or as one who learnt sufficient at school or elsewhere to realise dimly its importance. The former type is in a great majority, and it is mainly he who must be attracted and impressed. How can we approach him? What kind of reading does he prefer? The answer to the latter question is well known and writ large at the top of the columns of his daily newspaper: anything that appeals to his primitive instincts. Personalities and abnormalities, matters relating to material gain, sex, sport, fighting, and adventure: these are the main excitants. Emotion, not reason, being the keynote of his mental disposition, he must be approached through his affects. Unfortunately, the writer of popular science has only a few instincts to play upon, such as wonder, acquisition, and construction, but if he is skilful he can turn these to good account. (In this connexion it is noteworthy that the scientific topics that have been most reported of late are, Mars—mercury from gold—wonders of wireless—determination of sex.) Further, our man in the street dislikes being preached at. He has little regard for unembellished statements of fact: he must see their bearing, actual or potential, on his daily life. For historical data he does not care, and of abstract thought he is usually quite incapable. So far as possible, things must be presented to him in concrete and predigested form. Hence the language to be addressed to him must be simple, concrete, and familiar; technicalities must be avoided, sentences should be short, and headings numerous.

If these comments and desiderata be conceded, only one general conclusion can be drawn concerning the pamphlets under notice: they are unlikely to appeal at first sight to the individual whose mental attitude has just been outlined. On the other hand, they should certainly be appreciated by the minority who have already a bowing acquaintance with science. As might be expected, there is a considerable diversity of merit, and it is not easy to generalise. It may, however, be said that the authors have succeeded in demonstrating the innumerable ramifications of chemistry and the ubiquity of the chemist. The most common defect is that the authors have attempted to tell too much: they have fired their facts straight at the reader as from a machine-gun, whereas they should have propelled them at an angle, like star-shells, to burst at intervals and illuminate the scene. Further, they have not made enough of the human factor, and have not appealed sufficiently to the wonder instinct of their readers. In some cases the composition is defective; the golden rule to use the concrete noun and the active verb wherever possible has been neglected, and windy circumlocutions are numerous. we read: "The cultivation of these plants is p cuted" [These plants are cultivated]; "A great am of careful consideration" [Much careful thou "Titanium dioxide has remarkable opacity, and feature is utilised in its employment for pig purposes" [Titanium dioxide is remarkably op and therefore very useful for making pigments]; " platinum acts as a catalyst . . . without sen alteration to its own character" [. . . without u going change].

The pamphlet entitled "The Quest for Colour" far the most attractively written; its author s literary gifts, not the least of which is imagina and he makes skilful use of analogy and allusion. has selected his material with excellent judgment not overburdened his interesting story with a multi of superfluous facts, and he has written an essay w every educated man, whether he have knowledg chemistry or not, will delight in reading. Of a diff and more academic type is "Chemistry in Relati Food," the author of which has made full use o intimate relation of his subject to everyday life. has wisely omitted historical references, and th he has produced rather strong meat for the ge reader, his matter is very interesting and well b out the value of chemistry in safeguarding the p of our food supplies. "Chemists and their Work somewhat disappointing, as one hoped—per wrongly—to find in it some pithy remarks on psychology of the chemist; and the opening state that "Chemistry is the key to modern prosperit modern civilisation" is too bombastic even for E bition literature. The author has, however, succe in conveying his information in simple language, his story, though somewhat sketchy, is distin readable. "Fine Chemicals" and "Wood Produ contain fluent accounts of these important mate which will be appreciated by those who already some knowledge of chemistry; and the same ma said of the pamphlets on "The Heavy Che Industry" and "The Fermentation Industries," w are bursting with information and written in too bose a style. Judicious pruning by the editorial would have greatly improved these two pamph The writer of "Chemistry in the Manufacture of ments, Paints and Varnishes" is an acknowle authority on these materials, and his articles are alw worth reading; but although he has many interes things to relate in his pamphlet, he cannot be sai show the gift of popular exposition.

It seems, therefore, as if the scientific worker is well fitted, either by nature or nurture, to play cessfully the part of propagandist to the man in

st et. He is usually too academic, too objective, too ch devoted to statements of fact and too little to ing. A popular appeal must be through the human rt and by the stimulus of the spirit of discovery. Is not necessary to adopt the specious methods of politician or the sensational style of the popular ss, but the gospel of science can be taught only by apostle who realises that " il ne s'agit pas de parler, 'agit de persuader ; il ne s'agit pas d'écrire sur du ier, il faut écrire dans les cœurs."

The Analysis of Sound by the Cochlea.

e Mechanism of the Cochlea : a Restatement of the Resonance Theory of Hearing. By George Wilkinson and Dr. Albert A. Gray. Pp. xx+253+4 plates. (London : Macmillan and Co., Ltd., 1924.) 12*s.* 6*d.* net.

THE means by which physical stimuli are converted into sensations are always the subject of controversy. So far as the recognition of the physical vents is concerned, it is undesirable that the intermediate processes should obtrude themselves on the observer's consciousness ; nevertheless, the mechanisms interpretation form a fascinating, though difficult, bject for a physiologist.

In order to understand the whole process, one must now the applications of physics to the subject of scussion, as well as have a sound knowledge of the inute anatomy of the interpreting organ, and of the ysiology of the nervous system.

Drs. Wilkinson and Gray have presented a readable tline of the mechanism of the cochlea. They quite ghtly exclude all hypotheses which place the mechanm of analysis in the brain. The presence of such a mplicated organ as the cochlea would be quite unecessary if the nerves merely conveyed a complicated eries of impulses corresponding to the waves of pressure the air, and so far as all physiological evidence goes, ne nerves are incapable of conveying impulses of such igh frequency as occur in sounds of high pitch. In fact, such hypotheses are merely a confession of failure o explain the mechanism.

Of all the analytical processes ascribed to the cochlea, he authors believe that the correct one is a resonator echanism. They point out that there is a progressive ifferentiation in the length and tension of the fibres of he basilar membrane, and in the load due to the liquid the cochlea from its base to its apex. Thus all the erms in the formula

$$\text{frequency} = \frac{1}{2 \times \text{length}} \times \sqrt{\frac{\text{tension}}{\text{mass per centimetre of length}}}$$

elp to make the basal end of the organ of corti resonate o high notes, and the apical end to low notes.

The authors commence by a description of the physics of sound and of the principles of resonance. This is followed by a brief outline of the evolution of the cochlea and a more detailed description of the mammalian cochlea. In the latter description one might expect to find some mention of the division of the basilar membrane into subarcuate (elastic) and pectinate zones, and some discussion as to the possibility of the rods of corti altering the periodicity of the resonating mechanism. Although the rods of corti are present only in mammals, they ought to have some influence on the analytical mechanism of those animals in which they are found.

Dr. Gray explains very clearly how it is possible that a note of a certain pitch can be recognised although the vibration of the organ of corti may be spread over a number of receptors : in fact, the more strongly stimulated receptors cause an inhibition of the sensations which might be produced by neighbouring less stimulated ones. One sees examples of such inhibition in other sensory mechanisms.

The authors doubt the adequacy of " sound picture " and " travelling bulge " hypotheses to explain sound analysis, and it must be granted that if the latter are to have any meaning, they resolve themselves into a process of localised movement of the basilar membrane corresponding to a resonance process ; otherwise, the distance that a wave travels up the cochlea should be a function of its amplitude and not its frequency.

Dr. Wilkinson describes the well-known model which he has made to illustrate the analysis of sound waves by a resonance system comparable to that of the cochlea, and the method of construction is given in an appendix. Such a model merely shows the possibility of the analysis by a corresponding resonance mechanism without proving that it is the only way in which the result can be obtained. The reviewer would point out that it is possible to differentiate frequencies of pressure waves by means of viscosity *in spite of* the inertia acting in the opposite direction. Thus, two tubes of the same length but of different diameters, united to a common tube, can be used. Pressure differences applied to the common end will cause movement of a contained liquid mostly in the wider tube, but if a small bulb closes the far end of the wider tube, and a large one the far end of the narrower tube, it will be found that low frequencies of pressure changes will cause most movement along the narrow tube, whilst high frequencies will cause most movement along the wider tube. The inertia for the same extent of movement should be less in the narrower tube, therefore this differentiation occurs in the reverse direction to what one would expect from the mass of liquid contained in the tube. It is in view of the fact that

friction may have some effect on the analysis of sound waves that the model described on page 104 differs from that of Lux and others. It may be true that viscosity has nothing to do with resonance, but there is a mechanism due to liquid friction by which analysis can be produced; this process may be supplementary to the factors discussed by Drs. Wilkinson and Gray.

The authors say nothing about the variations in area that occur along the scalæ of the cochlea, and these variations become significant in relation to viscosity effects.

This book should be read by all those interested in the problem of how sounds are analysed, and it gives a concise and adequate description of the various facts and hypotheses concerned in the action of the cochlea.

H. E. ROAF.

Diving in Birds.

The Bird as a Diver: a Contribution to the Natural History of Diving Birds. By Dr. John M. Dewar. Pp. xii+173. (London: H. F. and G. Witherby, 1924.) 10*s.* 6*d.* net.

DR. DEWAR has for many years been investigating in a quantitative way the problem of diving in birds, and more particularly the relation between the length of time spent under water and the depth of water. This book is a statement of his evidence and his conclusions.

The most important of these may be briefly summarised. The diving habit has been acquired independently several times over in birds. In spite of this, in five of the six families of birds studied by Dewar, the relation between time and depth is the same. Roughly speaking, it is 20 seconds for the first fathom of water, 10 seconds for each subsequent fathom. As a matter of fact, the data are more accurately represented by an S-shaped curve, with time as the abscissa. This, of course, is the curve of an autocatalytic reaction, and our author believes that the depth-time relation is determined by some autocatalytic reaction in the body. It is, however, equally legitimate (and more likely!) to suppose that there is some initial delay connected with "getting under way" subaqueously, and that below a certain depth each additional foot becomes more and more difficult. This would give a curve which, with the evidence here presented, it would be impossible to distinguish from the regular S-shaped curve of autocatalysis.

The coot alone, of all the birds studied (which included diving ducks, grebes, cormorants, divers, and auks), does not eat its food below water; it therefore has no "bottom time." The rough rule for the coot is 10 seconds for each fathom, including the first, but this species also shows the S-shaped curve.

From a study of the ratio between length of and length of pause, rate of increase of pause fathom of depth, and longest dive, it was possibl grade the diving birds for diving ability. The came out lowest, the auk highest, with the ot ascending in the order given in the preceding paragr

Numerous interesting points are brought out cerning under-water speed, greatest depth of (which is probably much less than is generally believ etc.; but the point which Dewar rightly empha as the most interesting is the fact that not merel similar but an identical time-depth relation has b independently evolved in at least five separate fam of birds under the influence of environmental similar

Although many will feel that a rather small si problem is here treated at somewhat excessive len the book is certainly a welcome contribution t scientific natural history, and shows what us biological work can be done by the field natura who is possessed of the scientific spirit and not of mere collector's instinct.

J. S. H

Regional Survey of Cambridge.

The Archæology of the Cambridge Region: a T graphical Study of the Bronze, Early Iron, Roman Anglo-Saxon Ages, with an Introductory Note on Neolithic Age. By Dr. Cyril Fox. Pp. xxv+36 37 plates+6 maps. (Cambridge: At the Univers Press, 1923.) 31*s.* 6*d.* net.

MAPS are the mainstay of this attractive volu on the antiquities dating from the later St Age to the Domesday Survey in a selected area, hav Cambridge for a centre. In a pocket at the end five tinted reproductions of the 1 in. Ordnance Sur map of nearly 2000 square miles, showing the distri tion of population and the natural features by wh that was determined in the various periods; there also sketch-maps in the text showing the relation this square to eastern England. These limits chosen not because they constitute a geographical u or area isolated by natural barriers, but because th include most of the localities which have furnished Archæological Museum of the University with mate here rendered accessible to students in more th the ordinary sense. The most interesting specim of the successive periods treated are represented 37 photographic plates, which have a home-ma appearance but are generally adequate, and bring light a good deal of new material. The text g further, and describes many finds preserved elsewhe but all part of the local story. Here, above all, author's industry and method are revealed and me general recognition, as the way is now indicated fo

si ilar treatment of other large collections. Seldom h e the utility and purpose of a museum been more p pably illustrated. Though much is gi o withheld—perhaps only temporarily. The region i ludes parts of Norfolk and Suffolk that swarm with f t implements, as the Neolithic map clearly shows; t this period is dealt with in 15 pages, and the Early S ne Age not at all. One has to confess that a Con- t ental work of this kind would have been better p portioned; and Cambridge has a mass of flint to i erpret to the world.

The careful study of museum specimens, the verifica- t n of their *provenance*, and the identification of others r t within the fold have led, as might have been ex- p cted, to important results; but the spade has many s surprise in store, and new light has recently been t own on the history of this part of England by the e cavation of the dykes or ramparts that form a series o barriers south of the Fens, and were evidently e ected against an inland people, as the ditch is to the s uth-west. Below the Fleam Dyke, for example, w re found Roman remains on the original surface; a d as there would have been no reason for such a work i the Roman period, it is now definitely referred to t e early Anglo-Saxon period and attributed to the E st Anglians, who did not trust their neighbours to t e west. Such vast earthworks can only have been c nstructed by large and organised communities; and t e next stage is to decide who were the people that t reatened to attack, and also at what moment the p sition became serious. History can here derive m uch assistance from archæology; and Dr. Fox has p inted out the military value of these lines across t e main road in open country between Newmarket a d Royston. Traffic flowed at right angles to this r ad in Roman times, and the crossing of two R oman highways was evidently the nucleus of C ambridge.

In striking contrast to the other four is the map of A nglo-Saxon settlements, on which the Domesday Vills a re uniformly scattered over what a few centuries before h ad been dense woodland on a clayey soil, difficult to c ultivate and dangerous to traverse. The same might b e thought to hold good of the Fens, but large areas i n the south-east of that formation were evidently i habited in the Bronze Age, and must therefore have s unk in the last 3000 years.

The work is planned on a generous scale, and Dr. F x's thesis has not only benefited himself but has also d one excellent service to the Museum with which he i s connected. It is no small achievement to have r alised the golden mean between the superficial guide- b ook and the voluminous and often unreadable cata- l gue. Museum curators, please copy.

Our Bookshelf.

A Textbook of Petroleum Production Engineering. By Prof. Lester Charles Uren. Pp. vii+657. (London: McGraw-Hill Publishing Co., Ltd., 1924.) 30*s.* net.

Oil production, like oil geology or oil refining, has undergone rapid development in method and technique during the last few years, and the profession of the petroleum engineer, formerly one of somewhat uncertain definition, is fast becoming one of specialisation both in training and accomplishment. The industry has in the past relied on, and still to a large extent relies on, the services of practical field-men who, though they may have years of experience behind them, lack the requisite technical education enabling them to assume control of large-scale operations involving a competent knowledge of the science of oil production. The demand for qualified men of this description has brought about the establishment of systematic academic training at several universities, especially in America, and the author, himself a professor in the department of petroleum engineering at the University of California, has designed this work as a text-book of reference for students reading for this particular faculty.

The book thus presents to a larger audience the substance of theoretical and to some extent practical teaching of this phase of engineering, in accordance with the curriculum laid down at that university, and as an academic conception of the subject it is well done. The plan of the work is to trace the various stages of field-operations from preliminary exploitation through the ramified processes of drilling and production to transport and storage of petroleum, each of which is treated in great detail. Unfortunately, being an academic treatise of an intensely practical subject, the text reveals the atmosphere of the class-room rather than that of the field, with the result that the large amount of descriptive matter tends to be formal, stereotyped, and tedious to read, besides conveying (doubtless unintentionally) the suggestion of orderliness in actual operations which is far from being the case. Perhaps this is more noticeable in view of the fact that Suman's recent and excellent treatise on "Petroleum Production Methods" has, by its essentially scientific though practical point of view, set a standard as yet unattained by any other work of its kind, not excluding the present volume. To be really successful, a book such as this must give a lead rather than follow precedent; the student of the future, even more than the trained man of the present, will need inspiration as well as guidance, suggestion of possibilities rather than mere digestion of technical data. H. B. Milner.

Analytical Conics. By Dr. D. M. Y. Sommerville. (Bell's Mathematical Series: Advanced Section.) Pp. vii+310. (London: G. Bell and Sons, Ltd., 1924.) 15*s.* net.

We welcome Prof. Sommerville's book as one of the most comprehensive English treatises on analytical conics. The author shows a wide, detailed, and accurate knowledge of the subject, ranging from elementary co-ordinate geometry to chapters on systems of points on a conic and invariants. A student wishing to acquire a thorough knowledge of the subject cannot do better

than work steadily through the book, but one desiring a light course only will need much guidance in deciding what portions to leave out.

Various points require some slight alteration. In the early pages the notation 2, 2 instead of (2, 2), for the co-ordinates of a point, is unfortunate, as a beginner will have to unlearn it later. The classification of curves given by real equations of the second degree (p. 114) is incomplete, no mention being made of $m^2x^2+n^2y^2+1=0$. It should also be noted that $ab=h^2$ is not a sufficient condition for a parabola, and, on p. 247, that the algebraic freedom-equations must be rational. A few results are stated incorrectly, *e.g.* No. 12 on p. 255. Neither is the distance of a point from a line in homogeneous co-ordinates found in the best way.

However, these matters are only minor blemishes which can easily be adjusted in a later edition. Scientifically the weakest feature is the treatment of complex geometrical elements. Although the author lays stress on the fact that he has written about geometry, and not about algebra with a geometrical interpretation, he is content to say that a quadratic equation with unreal roots defines two "imaginary points" on a real line and to assign to these points the qualities of real geometrical entities. But the treatment of complex geometrical elements is unsatisfactory in most English text-books, and the author of this one follows many precedents in the course he has adopted.

We cordially recommend Prof. Sommerville's book both as a work of reference for mature readers and as a text-book for students desiring to make a serious study of analytical conics. The numerous problems will be specially valuable to the latter. W. E. H. B.

Cancer: How it is Caused, How it can be Prevented. By J. Ellis Barker. Pp. 432. (London: John Murray, 1924.) 7*s.* 6*d.* net.

WE cannot agree with Sir W. Arbuthnot Lane that this book "will prove a great boon to mankind" or "that it is easily the most important practical work on cancer existing in English or in any other language." These statements are extravagant or, at least, very doubtful. Mr. Barker's book is the work of a journalist and is from beginning to end uncritical in a scientific sense. He states (p. 110) that he is "fully acquainted with the latest discoveries," but if so he has not given them to us but has used his book to express his opinions that cancer is due to constipation and lack of vitamins, two views which in our opinion have little foundation in fact. Almost the only authorities he quotes are surgeons—notoriously the least fertile of our medical researchers—whom he describes by some appropriate adjective such as great, very great, able, eminent, famous, or celebrated. Their statements, mostly from the general press, are regarded by Mr. Barker as an authoritative canon. We are reminded with irritative frequency that Sir W. Arbuthnot Lane has said, "Cancer never affects a healthy organ or healthy tissue." Sir W. Arbuthnot Lane may believe this, but it is our duty to point out that there exists a very extensive scientific literature for and against this opinion.

The whole aim of Mr. Barker's book is to put forward the pious belief—it is nothing more—that cancer is a disease of civilisation and is associated with constipation, which can be alleviated by eating raw food a roots like the beasts in the field. A great deal is m of the catchword "auto-intoxication." If Mr. Bar would like to know how little is the knowledge wh science possesses on intestinal auto-intoxication can commend to him the article by Dr. W. C. Alva in *Physiological Reviews* (1924, vol. iv. pp. 352-393)

In our opinion the book will do much more ha than good, as it can only have a deleterious action a make people concern themselves with morbid sympto in their abdomens. It may lead to a few intesti "kinks" being unkinked, but it is very improba that Mr. Barker's precepts will have any influence the incidence of cancer of the abdomen or elsewhere

Evolution at the Crossways. By H. Reinheimer. 191. (London: The C. W. Daniel Co., 1924.) 6*s.*

TWENTY-FIVE years of dietetic experiment have enal the author to frame new theories of evolution. Lik disciple of M. Coué, he states that to be true wh he wishes to be true, and produces a picture of world which will be pleasant to many.

"Selectionists . . . impute a very low kind morality to Nature—low enough to approximate ruthlessness of elemental forces"; but for Mr. R heimer "the roots of morality go back to the mut relations existing between the lowliest of organis the nitrifying bacteria." "Palæontology shows t those organisms which have aimed at a self-suffici life, have received no encouragement from Natu "Parasites are failing species." "An organism, order to persist on the road of progress, must seek provender amongst the spare products of anot kingdom." "Habitual predacity invariably leads protoplasmic impoverishment." For "the frugivor animals, including man himself . . . their high p rogative was purchased by biologically righte behaviour." "A carnivorous career necessitates inordinate supply of blood to the large fangs, whic the cause of the brain being fatally under-supplie (The relative brain-power of dogs and sheep is discussed.) Righteous birds feed on grain and fr and righteous insects on leaves. (The debt of a culture to unrighteousness is not discussed.)

Many will admire this book, whom we cannot rem that sharks are older than land-animals, and carnivor echinoderms older than sharks; that most animals in the sea, and of them nearly all larger than a r grain are carnivorous; that beautiful fish are not predaceous than ugly fish; and that the product of thousands of eggs for one to survive is not "a fo of disease and penalisation," but is repetition of ancient marine habit still followed by most fem animals, and by all males. G. P. B

Animal Life in the Yosemite: an Account of the Ma mals, Birds, Reptiles, and Amphibians in a Cr section of the Sierra Nevada. By J. Grinnell a T. I. Storer. Pp. xviii + 752 + 62 plates. (Berkel Cal.: University of California Press, 1924.) 7 dollars.

THE present volume describes a survey of the ve brate natural history of the United States Natio Park of the Yosemite region, the geology and bot of which had previously been explored. It was und

ken by the California Museum of Vertebrate Zoology, object being to learn the species and the local distribution of each, to map out the general life areas, learn the food relations and breeding habits of the species, and, finally, to present all in a form accessible the public, both lay and scientific. The section studied is divided into six zones, the characters of which are enumerated, the species found in each being shown pictorially; as the Sierra crest is 10,000 to 1,000 feet in altitude and the two sides of the divide differ greatly in aridity, there is clearly plenty of scope. Censuses of birds observed are recorded, numbers of each species seen in stated times and distances in each zone. The balance of Nature from insect to bird, bird to tree, and tree to insect is claimed to be mutually beneficial. Then follows a typical natural history account of each of the 246 species of mammals, birds, reptiles, and amphibians that were found, the book closing with an excellent bibliography and more than sixty well-chosen plates illustrative of the fauna. We should certainly have this book with us if we were visiting the Yosemite region, for, as a first complete work on the locality, it adequately fulfils its object. It will be a useful basal foundation for subsequent periodical surveys to ascertain the changes taking place in the Park due to the closer settling of neighbouring regions.

The Marine Plankton, with special reference to Investigations made at Port Erin, Isle of Man, during 1907–1914: a Handbook for Students and Amateur Workers. By Dr. James Johnstone, Andrew Scott, and Herbert C. Chadwick. Pp. xvi+194 (20 plates). (Liverpool: University Press of Liverpool, Ltd.; London: Hodder and Stoughton, Ltd., 1924.) 12*s.* 6*d.* net.

This is an account of the researches of the authors on the distribution and succession of the plankton in a particular area of the sea. Apart from the important data recorded here, the book gives an admirable account of how a research of this kind is and should be conducted. It can therefore be used as a preliminary guide by any one who wishes to pursue a similar research in other parts of the sea.

After an opening chapter on "The Plankton in General," a large series of illustrations is given of various plankton types. These enable the student to identify the main classes to which the organisms of a particular plankton sample belong. A chapter on the distribution in space of plankton and the succession of forms throughout the year then follows: this is based on the authors' researches. The last chapter gives an account of nutrition in the plankton and of organic production by plant and animal organisms.

There is a valuable appendix on methods to be employed, and a short bibliography from which further references can be obtained. The illustrations are very good. The reference to the quantum theory on p. 156 is perhaps rather out of place in a book of this scope; the account is necessarily too short to be clear, and does not really seem to be of importance to the argument.

This kind of book is unfortunately not common enough. One cannot help wishing that there were books of a similar scope and price to help the student of, for example, fresh-water biology.

The Principles and Practice of Fly and Bait Casting. By Reginald D. Hughes. Pp. xi+80+8 plates. (London: A. and C. Black, Ltd., 1924.) 5*s.* net.

Mr. Hughes is both a caster and an angler, that is, he is an expert in the art of casting for its own sake, without regard to its application to the sport of fishing, and also an enthusiastic angler, who has brought to the pursuit of his sport all the knowledge acquired in the practice of his art. His book, therefore, will be of the greatest service to anglers. It covers both branches of angling, dry-fly fishing, and fishing with bait, and in each case the general principles involved are discussed, and precise and careful directions given for both single-handed and double-handed rods. The veriest tyro can follow the author's instructions with ease, and should, by careful attention to detail and assiduous practice, acquire that precision in casting which will add to the pleasure of his sport and to the weight of his basket. Clear illustrations and drawings help the text very materially, and anglers will be grateful for the sound advice so clearly and concisely given. Casting is not fishing, as the author is aware, but that correct casting is the first requisite in the making of a successful angler, no one, least of all anglers themselves, will deny.

A Dictionary of Electrical Terms: for Electrical Engineers and Students. By S. R. Roget. Pp. vii+296. (London: Sir Isaac Pitman and Sons, Ltd., 1924.) 7*s.* 6*d.* net.

As many new branches of applied electricity are continually developing, new terms come into use, and it is difficult even for the professional electrician to remember what they all mean. This book of Mr. Roget's therefore fulfils a useful function. For example, it is no use to look up in an ordinary dictionary to find out what a traction engineer means by an "ear" or a "frog," or an illuminating engineer means by a "lux" or a "lumen." We are glad that the author includes American terms. Every electrician must now read a certain amount of American technical literature, and he might easily be puzzled by such terms as "resistor," "inductor," "quarter-phase," etc. We can congratulate the author on having got such a comprehensive list into such a small volume. It will prove useful to many.

The Racing Eight: Notes on its Design and Propulsion. By W. B. Coventry. Pp. iv+39. (Cambridge: W. Heffer and Sons, Ltd.; London: Simpkin, Marshall and Co., Ltd., 1922.) 3*s.* 6*d.* net.

Mr. Coventry's aim is to discuss how to obtain the maximum speed out of a racing eight. It is clear that the design of the boat is an important factor determining the success or failure of the crew, and the author claims that in several cases the result of the Universities Boat Race was due to the superior design of the boat used by the victors. His chief contention is that a racing eight should be as short as possible. He bases his view on theoretical grounds, as well as on the successes achieved by the short boats constructed by Mat Taylor of Newcastle for Oxford in 1857 and for the Chester Rowing Club in 1856. In his theoretical investigation he assumes that the resistance is mainly due to surface friction on the wetted surface, being proportional to the wetted area and to the 1·852 power of the speed. S. B.

Letters to the Editor.

A New Method of Investigating Sea Waves.

THE common methods of investigation of a high sea permit the height and the length of waves to be measured, but do not give any means of determining the changes of form of the wave, which can sometimes differ considerably from the simple form of a trochoid. "Forced waves" especially undergo deformation inasmuch as their steepness has often to be left out of account. Precise stereo-photogrammetric methods are always complicated, cumbersome and slow, which reduces their applicability to large amounts of material, as in other regions of geophysics. In such cases, when comparisons of the steepness of waves have to be made with large masses (as in the comparison of ocean and smaller sea waves) in order to study the relations between it and the wind-velocity, etc., the following method can be used.

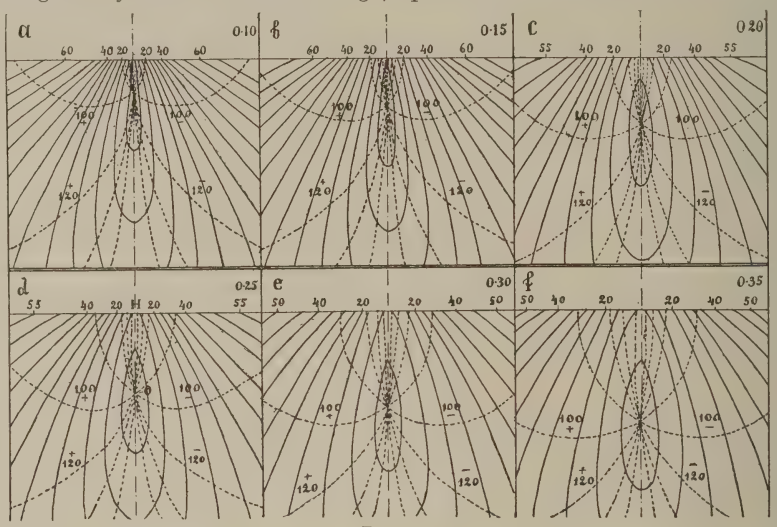

FIG. 1.

If rays from the sun fall upon a perfectly ca mirror-surface of water, an observer sees a sin reflected image of the disc of the sun (or the m may be used) at a point which makes with horizon the same angle downwards as the heave body is above the horizon. In reality, there generally instead of a single image a series of s shining spots, forming a shimmering strip upon waves through reflection of the luminary in numerable mirrors from differently inclined eleme of the sea waves. By following the rays of lig one can find the relation between the position o sparkle on the surface of the sea and the inclinati of the correspon ing element of t wave, as well the direction of path. To cre a clear picture a high sea it best to use a n of isoclinals curves of an equ inclination waves to the ho zontal plane) a isogonals (sho ing an equal rot tion of a wav element about t vertical axis) projected on t surface of the s in the place of t strip of glitteri spots under t sun (or moon). such a net, co structed by me by means of a very simple instr ment [1] for six different heights of the sun (Fig.

FIG. 2.

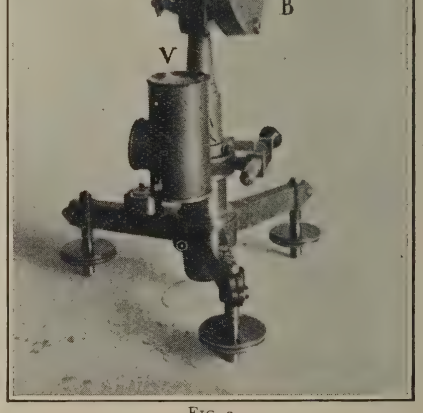

FIG. 3.

may be superposed a photographic negative of th light strip on the sea surface.

[1] Was. Shoulejkin, *Nautical Magazine*, 1924, and Hydrographic Memoirs of Russian Hydrographic Office, 1924.

The scale of nets (Fig. 1) may be such that the distance *HO* (Fig. 1, *d*) is equal to a quarter of the focal length of the apparatus used in taking the photographs. As an example, I give here a photo (Fig. 2) superposed on a net. As will be seen, the predominating steepness of the waves is here equal to 15°. The steepness of small waves arising from the surface of the chief waves is nearly 35°. A gush of wind is evidently creating capillary waves with an azimuth +120°, as can be seen from the sparkles superposed upon corresponding curves.

If observations are made, not from a ship, but from the sea shore, photographs are unnecessary; it is sufficient to project a corresponding net of curves (Fig. 1) directly on the sea surface. For such observations I have constructed an instrument, illustrated in Fig. 3. In the field of the eye-piece, *O*, of the tube *OS* is placed a revolving disc (enclosed in the round box *B*) with six sets like those of Fig. 1. The observer rotates the instrument about the vertical axis until the image of the sun's (or moon's) disc appears on the control-line of the ground-glass (*V*). On this control-line are marked six points, corresponding to six particular heights of sun, and provided with the same numbers as the sets of the revolving disc. After noticing at which of the points the sun's image is situated, the observer brings into the field of view the net with the corresponding number, and he can then easily find the steepness of the waves as well as their direction.

It would be of interest to make observations of the influence of wind-velocity, and of the depth and size of the basin, on the steepness of the waves, possibly on a large scale, by means of this simple method.

The "Ship-designs" on Prehistoric Egyptian Vases.

THE interpretation of the ship-like designs painted on the light-brown vases of prehistoric Egypt, such as those figured by Sir Flinders Petrie on plates xix.-xxii. of his "Prehistoric Egypt," has given rise to considerable discussion. These designs, which have been considered to be "stockaded forts," "barbaric designs of boats," or "sea-going galleys," present a more or less curved structure from which a long series of tall columns or "fringe-like lines" (Budge) depend from its under margin at about equal distances apart. Those who adopt the boat interpretation consider these fringe-like lines or columns to be oars. Others interpret them as sand-ripples. Upon this curved structure stand two erections designated "cabins" by some writers; by others as "two blockhouses forming a pylon entrance." They stand on each side over above a gap in the pendent series of fringe-like lines. The majority opinion supports the view that these pictures are ship-designs; but many find it difficult to convince themselves of the reality of this interpretation for several reasons.

The body of the structure, or platform, is certainly boat-like and is probably modelled upon a boat; but the pendent columns, which obviously have no resemblance to oars, all originate from the lower margin of the platform and are never shown reaching as high as the gunnel level, which they would naturally do if they were oars; nor in any of the designs are there ever any indications of rowers. The number of the pendent fringe-like lines, which varies from 30 to 70 on a side, is out of all proportion to that required as oars, even if the structures represent sea-going galleys. Moreover, 60 to 140 sailors could not be accommodated, not to speak of their oaring, in the space provided for them on any of the crafts pictured. Sir Wallis Budge, while accepting the adscription of these structures to boats, considers the "fringes cannot represent oars," but "the water through which the boat is passing." If the fringes be not oars, it seems to me that the rest of the picture can scarcely represent a boat. The identification of the fringes with water, however, fails to explain the invariable behaviour of this element in spacing itself opposite the cabins on the deck; or why in Vase Brit. Mus. 32,639 the usual hieroglyphic for water, employed in the upper part of the panel, is so different from the "water" of the fringe-like lines.

Since the pottery decorators of the period knew quite well how to delineate "with unusual delicacy and spirit" boats with boatmen in action, and in appropriate number, as plate xxi. 46K of "Prehistoric Egypt" attests, it is difficult to understand why artists so capable should draw such barbaric objects if they intended them to be boats. These pendent columns (*tom. cit.* plate xix. 40M) are frequently represented, by the usual hieroglyphic, as set in water. Although this sign is often omitted it may be taken for granted, since all these ship-designs are so similar, that they all bear the same relation to water, associated as they are so frequently with a long-legged wading bird—the flamingo. I suggest that the associated flocks of flamingoes supply the key to an interpretation of the designs in question somewhat different, I believe, from any so far proposed. It is important to note that the birds are flamingoes and not ostriches. "The Cambridge Ancient History" (i. p. 570) and Sir Wallis Budge (Brit. Mus. Guide to the IV. etc., Egyptian Room, p. 247) designate these birds ostriches.

In 1909 I suggested in NATURE, with regard to the same scenes, that the birds were flamingoes, not ostriches, a view which has been accepted by Sir Flinders Petrie and others. The scenes under discussion are much too watery for birds with feet adapted to the hot desert sand. The pictures are consequently not river scenes, which flamingoes do not frequent, but shallow lagoons, or inundated marsh lands beloved of these birds, which are here seen at home, and not passers-by on the wing, or casually resting. In such lagoons surely (since the water does not reach half up the flamingoes' tarsus) it would be impossible to navigate a craft requiring 140, or even 70 oarsmen. The figured structures therefore, I suggest, are not craft either for river or sea navigation, but represent in front view, perspective disregarded, watchers' naviform pile-platforms or hunting-lodges supported on reed piles set up in the delta lakes or the marshes—hunting-grounds from time immemorial. On plate xix. 41U (*tom. cit.*) there are seen the halves of two mounds of concentric wavy circles, which might excellently, and probably are meant to, represent, in plan, flamingoes' nests, which, as is known, are composed of mud built up in zones of decreasing diameter to a summit depression a couple of feet out of the water.

The ruminants pictured in the same scenes, and in some of them apparently inside the "lodge," probably represent animals—including a flamingo—either captured and imprisoned for domestication, or subjects for capture still feeding in the fens. The flowering plants so often figured in relation to these ship-designs seem to me (if I may dare to differ from a botanist so well versed in the African flora as Prof. Schweinfurth) scarcely to represent the aloe, a plant with which I was familiar in Sokotra, where, as in Egypt, it was hung as a charm over the doors of houses. Only one flower stalk arose from each root-stock; in these scenes there are sometimes more than one. Besides, the habitat of the aloe is in dry, rocky or sandy situations; a flamingo-frequented

marsh would not suit it. The figured vegetation recalls to me rather foreshortened date-palms with branching fruiting stems, showing in addition the cabbage—prized as a vegetable—in the crown of the palm. Sir Flinders Petrie, however, is of opinion that they are "aloes in tubs or vessels around which the leaves hang," as they are "never represented as springing from the ground." If so, the tubs must be standing in the watery mud. The stem of the plant (Petrie's "tub" I take it) shows palm-like growth-rings; and though it does not reach the water or ground, neither do always the "oars," the birds' or the ruminants' feet. The fan-like objects (*tom. cit.* plate xx. 44D) among which the flamingoes are wading, appear to me to represent young palms growing from the nut (which in palms sprouts without necessarily being covered) in or on the edge of the water, as I have seen them throwing up a single leaf on the marshy edge of the river of Hadibu in Sokotra.

The two erections midships on the deck (resembling cabins on paintings of unmistakable boats), each flying its Nome ensign, may be entrance gateways, or perhaps shelters. The gangway between them is invariably situated over the gap in the piles, the discontinuity of which would facilitate landing at the lodge from a reed-bundle float or small boat, or afford a passage-way underneath the lodge. The overhanging branch at one end may serve for shade—perhaps branches with dates for refreshment—just as it does at the look-out end of navigable Nile boats; while the tying-up rope dangles from the stem for the purpose of mooring any visiting boats.

Beaconsfield, Bucks.

The Supposed Constancy of the Hybrid between the Common and the Water Avens, *Geum urbanum* × *rivale*.

IN several publications issued during the last few years,[1] M. L. Blaringhem has asserted that the hybrid *Geum urbanum* × *rivale*, sometimes described as *Geum intermedium*, retains its character unaltered during subsequent generations, and he cites this plant therefore as an example of the constancy of an interspecific hybrid. In making this assertion M. Blaringhem neglects to take account of the result of experiments carried out by us,[2, 3] which are in direct contradiction to the view he puts forward. We should like therefore to direct attention to the facts observed by us and confirmed by further experiments.

Our observations were made quite independently, and have resulted in the establishment of the fact that a distinct segregation of characters takes place in the f_2 generation of this hybrid. This segregation concerns a considerable number of characters.

1. The *inclination of the peduncle* varies both towards the pendant condition of *G. rivale* and equally towards the erect position of *G. urbanum*.

2. The *presence of anthocyanin* in the peduncle and calyx, which the f_1 generation inherits from the Water Avens, varies considerably in degree in the f_2 generation, and this colouring matter may be almost absent in some specimens.

3. The *calyx*, which is more or less expanded in the f_1 generation, shows this condition in the majority of cases in the f_2 generation, but some individuals possess the closer calyx of *G. rivale* and others the reflexed calyx of *G. urbanum*.

4. The *colour of the flower* in the f_1 generation partakes of the character of both parents, the petals being yellow on their inner and red on their outer surfaces. In the f_2 generation there is a distinct segregation of yellow colour, about 75 per cent. having this colour and 25 per cent. lacking it, according to observations of one of us. This proportion agrees with the Mendelian ratio 3 : 1. The red colour varies considerably in degree in f_2, but scarcely any individual is found to lack this colour entirely. This may be explicable by supposing this colour to be due to several factors.

5. A segregation is also presented by the *form of the petals*. Thus, one of us has shown that in the f_2 generation 49 individuals had notched while 159 had entire petals, figures which approximate very closely to the Mendelian ratio of 1 : 3.

6. The *stipules* were observed to show considerable variation in size in the f_2 generation, tending towards those of the respective parents.

It seems curious that, in spite of such obvious segregation to which we have directed attention, M. Blaringhem should still maintain the former his erroneous view that *Geum urbanum* × *rivale* is an example of the constancy of hybrids between different species. This is all the more remarkable as M. Blaringhem admits in his publication of 1922 the occurrence of some variation in this hybrid. We can only imagine that he has not recognised that such variation is due to segregation because some of the characters may be due to two or more factors; so that to obtain completely recessive forms it is necessary to cultivate a very large number of individuals.

As M. Blaringhem's erroneous view of the constancy of hybrid *Geum urbanum* × *rivale* may gain currency among those who are not familiar with the progeny of this plant, it seems desirable to direct attention to the results of the experiments carried out by us prior to the publication of his conclusions.

Fine Structure of X-Ray Absorption Edges.

IN the issue of the *Zeitschrift für Physik* for July 1924, Dr. Coster reports the existence of a white line on the long wave-length side of the absorption edge in the case of the higher valence forms of various elements. Evidence has been obtained in the laboratory that iodic acid and potassium permanganate, two of the substances for which he reports this line, are slowly reduced by X-rays. If this occurs in the absorbing screen, it seems reasonable to expect that the photographic plates will show not only the absorption edge of the original compound, but also that of the reduced portion. According to Lindh's results with phosphorus, sulphur, and chlorine, the absorption edge of the reduced form might be expected to fall on the long wave-length side of the main edge. It seems reasonable, therefore, to raise the question whether the white line Dr. Coster reports may not be the absorption edge of that part of the material in the absorbing screen reduced by the X-ray.

In the effort to discover whether reduction of iodic acid could be demonstrated chemically, we have sealed portions of a 25 per cent. solution of iodic acid in water in thin walled glass test-tubes, with suitable precautions to prevent reduction by the heat of the blast lamp. In one of these tubes of iodic acid

ced a cubic centimetre of chloroform and in ther an equal amount of carbon tetrachloride, both which give a pink coloration in the presence of iodine. The other tubes contained only iodic and were broken open and tested with chloroform after X-raying for a number of hours. All the es gave the test for traces of iodine after exposure the X-rays. Solid iodic acid crystals take on a wnish coloration when X-rayed, but it has not been found possible to demonstrate conclusively at this coloration is due to free iodine. A very ute solution in water of potassium permanganate s found to have lost its pink colour and to have come distinctly yellow after being exposed to rays for an hour, thus indicating reduction of the rmanganate ion.

A little evidence has also been obtained on the ectrographic side. We have taken plates of the ilic acid L_3 absorption edge with a Siegbahn ectrograph, using two different absorbing screens, e containing iodic acid free from all traces of iodine the chloroform test and the other containing iodic id contaminated with traces of iodine or iodide. he white line on the long wave-length side of the ge was more pronounced with the impure iodic acid.

The spectrographic data available would also seem support our hypothesis in that it shows a rather markable agreement between Dr. Coster's values for e white lines with highly oxidised compounds and e values for the absorption edges with the free ements. In the case of iodic acid, he gives 11·5 X units for the white line and 2712 for the sorption edge of free iodine. For tellurous acid, reports the white line at 2846·9 X units and his alue for the edge of metallic tellurium is at 2847·1. e have just obtained the absorption edges for etallic antimony and metallic tin, and the agreement ith the white lines Dr. Coster reports for the idised compounds of these elements is equally riking. He reports white lines at 2991·1 and at 147·5 for the oxidised compounds, and we have und the absorption edges for the free elements at 991·5 and 3146·9 respectively. Thus, in the case of l four elements, the absorption edge for the free ement is within a fraction of an X unit of the value r. Coster gives for the white line. This, coupled ith the fact that X-rays can act as a reducing gent, would seem to be definite evidence in favour f the hypothesis that a part of the highly oxidised mpound in the absorbing screen is reduced and at the white line reported is the absorption edge of e reduced portion. Low-Voltage Arc Spectra of Copper and Silver.

IN NATURE of July 21, 1923 (vol. 112, p. 100), was ublished a letter from me giving results I had obained on the ionisation potentials of copper and silver apour by the low-voltage arc method. The spectroopic examination of these metals is complicated y the fact that the spectrum of the ordinary arc ontains large numbers of spark lines. By using a hree-electrode arrangement *in vacuo* such as was sed by Foote and Mohler, I have succeeded after ome difficulty in obtaining spectrograms of the ltra-violet arc spectrum of silver vapour entirely ree of spark lines. The only lines appearing are the irst two pairs of the principal series. The wavengths of the second pair, as measured by Pina, are ot correct. The small quartz spectrograph which as used in these experiments, and was in perfect focus, gave values always within 0·1 Å of the calculated wave-lengths quoted by Fowler. This is sufficient evidence that the value of the ionisation potential given in my former letter is incorrect.

The arc spectrum of copper is, of course, complicated by the presence of at least one "X" level between $1S$ and $1\pi_1$, which makes it possible for arc lines other than principal series lines to appear below the limit of the subordinate series at about 3145 Å. The arc in vapour at 8 volts gives a large number of lines terminating with a single line. This line I have measured on five plates of the ordinary arc, and have obtained values 2024·30 Å, ·35, ·30, ·34, ·36, giving an average of 2024·33, the value calculated for $1S - 2\pi_1$. This line is very strong in the low-voltage arc and it certainly cannot have any accompanying line of comparable intensity at 2025·67, the wave-length calculated for $1S - 2\pi_2$. This throws much doubt on the accepted interpretation of the X-combinations leading to these values.

The three-electrode apparatus which gave only arc lines in silver shows the copper lines given in List I., when operated at 8·2 volts and 6 m.a. These lines are almost certainly arc lines, and must, therefore, be combinations either with $1S$ or with terms of type X. They should be important in the disentanglement of the copper arc spectrum.

List I.

2165·08	2824·42
2179·39	2883·00
2181·74	2961·19
2225·68	3010·90
2230·11	3036·09
2441·67	3063·41
2492·15	3247·55
2618·39	3273·96
2766·38	

List II. contains lines extra to List I. which appear on a plate taken with an 8-volt arc in copper vapour. These lines must be either arc lines or easily excited spark lines. The wave-lengths are those given by Huppers. All the lines are so faint that intensities cannot very well be given, but the very faint lines are indicated with an f.

List II.

2024·33 (calc.)	2238·46 f
2138·54 f	2244·22 f
2199·64	2260·48
2214·58	2263·07 f
2215·68	2293·85
2227·74	2392·64
2236·28 f	2997·38 f

The difficulty of obtaining spectrograms of the visible region is much greater because of the high temperature of the filament and furnace, and so far only one rather unsatisfactory photograph has been obtained. It is hoped, however, to cover this region in the near future. A. G. SHENSTONE.

University of Toronto,
August 18.

Organisation in Chemical Societies.

IN common with all other members of the Chemical Society, I have received a notice to the effect that there is to be a virtual increase in the annual subscription, in that an extra charge will be made for the Annual Reports, which have hitherto been supplied to members free of charge, and at the same time directing attention to the need for increasing the membership of the Society. I have little doubt that the result will be that many members of the Society will not purchase the Report; but as this publication appeals particularly to students, and as it is from men

of this class that the Society should draw its new members, I fear that the new policy will defeat its own object.

I take this opportunity of directing attention to the position in which the lack of organisation in the chemical world places the younger men, and in particular those who are entering industrial life. The young industrial chemist may be expected to belong to the following organisations, and to pay the corresponding subscriptions, in addition to entrance fees, which I have not set down :

The Chemical Society . . .	3*l.*	0	0
Institution of Chemical Engineers .	5*l.*	5	0
Institute of Chemistry . . .	2*l.*	0	0
Society of Chemical Industry . .	2*l.*	10	0
Faraday Society	2*l.*	0	0

The total amounts to an annual charge of nearly fifteen pounds, and in addition there will be the subscriptions to be paid to one or more specialised organisations.

Between them these societies do not possess a library which is in any way comparable with the Patent Office Library, or a lecture hall which will accommodate even a moderately well attended meeting ; no set of *abstracts* comparable with "Chemical Abstracts" of the American Chemical Society is published in the country. These are hard things to say, but it is time that attention was directed to the facts.

A recent attempt of my own to recruit for one of our societies met with failure, as my intended victim pointed out that "he had the use of the Patent Office Library free, and generally preferred to attack his chemical literature through the publications of the American Chemical Society." Will any chemist suggest a suitable reply ? I have not been able to think of one.

When reorganisation of the societies connected with chemistry is suggested, it is always stated that it is impossible to raise the money which will be required. I have had a good deal to do with the raising of money for such objects, and there is one thing I know in connexion with the matter. It is this. If you want to raise money you must show that you are spending what you have got economically. You must also show that you know what you want, and what you are going to do with the money when you get it. If, as is rumoured, schemes for reorganisation are under consideration, it is well that they should see the light of day in a form in which they can easily be understood, and as soon as possible.

Surface Tension and Fine Particles.

THE formation of colloidal particles is undoubtedly influenced greatly by the forces of surface tension, which will tend to cause the coalescence of fine crystals into small amorphous bundles probably spherical in shape. An elementary investigation into the forces at work shows that the activity due to surface tension effects, when one is dealing with very small particles, may be very much more pronounced than is the case with our usual observation of larger masses.

If we consider the case of two equal small spheres of matter brought together, for example, two small drops of water in air or two colloidal particles in a liquid, surface tension forces tend to make them coalesce into one body having the least possible area. The action is regulated by the law that the reduction in the potential energy of the surface is equal $T \times \Delta A$, where T is the surface tension between surface of the particles and the surrounding medi (supposed constant) and ΔA is the change in a due to coalescence. The total change in energy then proportional to the square of the radius of particles (r). This change of energy is the seat the force pulling the particles together and deform them into a new shape. As energy has the dimensi of FL, we have a quantity of dimensions (FL) vary as r^2, and consequently the force involved will va as r. Now force induces in mass an acceleration, a consequently the acceleration (a) produced by surface tension action is such that $a \propto F/m$. Si $F \propto r$, and $m \propto r^3$, the acceleration produced var inversely as the square of the radius of the particle

Although, of course, no definite acceleration c be determined in any particular case, the above sho that what we might call the "activity" of the eff of surface tension on small particles will vary inversa as the square of the radius of the particles and, very small ultramicroscopic particles, the rapid of this action will be far beyond anything that we acquainted with in ordinary macroscopic observati

The "Hole, Slot and Plane" Geometrical Constraint.

A DETAIL in the "hole, slot and plane" geometri constraint (which is one of the commonest forms the "six point support" mentioned in Sir Geo Greenhill's letter in NATURE of September seems often to be described and constructed wrong. In this constraint, one contact occurs between rounded projection on one body and an approximat "plane" part of the second body ; two conta occur between a rounded projection and the si of a groove or "slot" ; and the remaining *th* contacts should therefore be arranged to occur the "hole."

The "hole" contact should not consist of a coni point resting in a conical hole of larger angle ; contact would not occur at three places, and the t cones cannot be made accurately right to their apic If a conical projection be used, resting in the end a simple circular cylindrical hole, contact would general occur at two places. If the axes of the co and cylinder were coincident (or if a sphere w used in place of the cone), line contact would th retically occur, the actual places of contact dependi in practice on the accuracy with which the surfa were shaped. The *three* contacts at the "hol could, however, be made by using a spherical conical projection resting in the end of a hole triangular transverse section (or resting on th spheres or three cylinders attached to the seco body).

The Large Black Slug at Honolulu.

LAST month, when in the Mansa Valley, Honolu Hawaiian Islands, I became acquainted with the lar slug which is now common in that locality. A livi specimen was handed to me by Dr. Robert Faus, a later Dr. Montague Cooke gave me a good series fr the collection of the Bishop Museum. Until rece years these slugs were unknown in the islands, and

doubt remained that they had been introduced. Nevertheless, as Dr. Cooke informed me, no one knew whence they came, or what (if any) described species they represented. I find that they agree with *Veronicella levdigi*, described from specimens collected at Brisbane, Queensland. Simroth, who made the species known, gave good coloured figures, and figured the anatomy. Henry Tryon (1899) gave a popular account of the slug, showing that it was destructive in gardens. Both he and C. Hedley were of the opinion that the animal had been introduced from some unknown locality. Dr. Willey found specimens at Vasafate, New Hebrides, and this may be the original home.

The species will be known by its large size, dark colour above, with a slender yellowish line; more or less black beneath (as well shown in Simroth's figure), with pale sole. I described the living specimen thus: Upper tentacles black above, dull yellowish below; lower tentacles stout, pale basally, black at apex; back dull black, with a slender broken pale ochre-tinted line, best defined posteriorly; underside black, with the sole dull pale yellowish; length about 80 mm., width about 25 mm., width of sole about 13 mm. Internally, a noticeable feature is the great length of the filiform glands. Probably this slug has been carried to other places, and it will be of interest to record new localities, should they be found. The specimens described by Simroth were not of full size, but the large size of well-grown examples is shown by Tryon, who gives a good photographic plate.

The Preparation of Line Sources of Radium C.

WHEN an active line source of radium C is required, the usual method of preparation is to seal a platinum wire into the end of a glass tube. Radium emanation is pumped into the tube with mercury, the wire being made the negative electrode with the mercury just beneath the wire forming the positive electrode. After a sufficient exposure, the emanation is pumped off, and the glass tube broken to remove the source. Even with quantities of emanation so small as 10 to 20 millicuries, the efficiency is very low, only 10 to 15 per cent. of the active deposit being found on the wire. This low efficiency is probably due to the distribution of the potential gradient along the wire. The drop takes place between the end of the wire and the mercury, while in the upper part of the tube there is practically no potential gradient. Thus most of the emanation is in a "dead" space.

The efficiency may be increased fourfold by the following device, which has been in use here for some time with satisfactory results. The wire is sealed into the tube as before, and a thin foil of iron or nickel, which will not contaminate the mercury, is slipped into the tube, forming a cylindrical sheath around the wire. The emanation is pumped into the tube and the mercury level raised until it makes contact with the sheath. The wire is made negative and the mercury and sheath positive. 110 volts gave 40 to 45 per cent. of the active deposit on a wire of 0·4 mm. diameter; 200 volts gave an efficiency of more than 50 per cent. The tube should be of not less than about 7 mm. internal diameter, and the foil should fit as snugly as possible against the wall right up to the end of the tube.

Recent Work at Stonehenge.

THE extremely interesting article of Col. Hawley in NATURE of September 20 leads me to ask him two questions which are raised by it:

(1) Were the Bronze Age interments found on both sides of the rampart, or only on the outer side?

(2) Are the "Aubrey Stones" contemporaneous with the main structure of Stonehenge, or were they a subsequent addition?

A description of Stonehenge has long been recognised in Diodorus Siculus (ii. 47), which he derived from Hecatæus, a writer of the 6th century B.C., "& some other" authors. We are told that it was dedicated to Apollo, the sun-god, in whose honour a great festival was held every 19 years which lasted from the summer solstice "to the rising of the Pleiads." We are further told that in the immediate neighbourhood was a city inhabited by the priests and their disciples, who worshipped the god daily with hymns and the harp. It would seem to follow that in the time of Hecatæus or his authorities the sacred precincts of the temple could not as yet have been desecrated by cremation burials.

A. H. SAYCE.

8 Chalmers Crescent, Edinburgh,
September 23.

THE Bronze Age interments referred to by Prof. Sayce occurred both on the inside and outside of the Stonehenge rampart, but by far the greater number were on the inside and at the bottom of the slope. Here there is loose soil about 14 inches deep of humus and chalk rubble, affording easy digging, in which the remains had been deposited without any attempt to make a cist to contain them.

Occurrences of interments on the outside of the rampart were six in number, but the remains were deposited with greater care. They were found at the top of the silt which had filled the ditch, and were placed in bowl-shaped cavities excavated to about two feet from the surface where the rampart slope joins the silt. Owing to deeper burial, they were better preserved and were coated with a thicker deposit of lime than those found inside: they were also greater in quantity and probably represented the remains of an entire body, whereas those on the inner slope were mostly only portions of cremations.

The Aubrey Holes were evidently of Pre-Stonehenge date, as the stratum of that period passed over them and the chips characteristic of it were not found in the soil filling the holes. They were evidently open holes during the neolithic period, for in one of them there was a quantity of chips which had been discarded by an implement maker and evidently struck from one large piece of flint. Some of them can be fitted together, and when so placed it is interesting to see where the blow was delivered to detach them. There is a description with drawings of twenty-three of these holes in a report to the Society of Antiquaries given in the *Antiquaries' Journal*, vol. 1, Part 1, of January 1921.

I have read the supposed description of Stonehenge given by Hecatæus of Miletus, but regard the existence of a city anywhere near here to be impossible. There are no Bronze Age settlements very close, and those with which I am acquainted in the neighbourhood must have been extremely primitive and rough: very dirty too, if one may judge by the refuse of black ashes, animal bones, and sheards of badly baked pottery strewn about them.

WILLIAM HAWLEY.

Asiatic Expeditions of the American Museum of Natural History.

By Dr. HENRY FAIRFIELD OSBORN.

THE Third Asiatic Expedition was projected in the year 1920 as a sequel to American Museum explorations in Japan, Korea, China, and Mongolia, collectively known as the First and Second Asiatic Expeditions. The first and second expeditions were purely zoological in purpose; the third was planned to occupy the very much wider field of geology, palæontology, botany, zoology, and anthropology. The leader of these expeditions, Roy Chapman Andrews, crossed Mongolia during the season of 1919 and observed that the broad level stretches of the Gobi Desert, bordered with gentle terraces, lent themselves to exploration by automobile as well as by the older method of camel transportation, and he conceived the plan of a geological and palæontological expedition

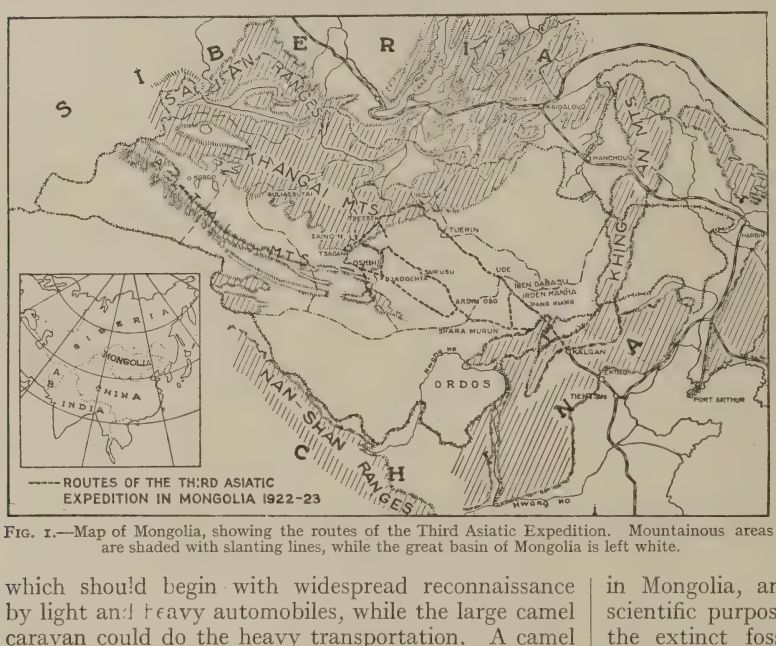

FIG. 1.—Map of Mongolia, showing the routes of the Third Asiatic Expedition. Mountainous areas are shaded with slanting lines, while the great basin of Mongolia is left white.

which should begin with widespread reconnaissance by light and heavy automobiles, while the large camel caravan could do the heavy transportation. A camel caravan travels two and a half miles an hour, fifteen miles a day; a well-equipped automobile train is capable of ten times this speed. This plan promised a double advantage over the work of previous explorers who had crossed the Gobi with only a camel transport, namely, Raphael Pumpelly (1864), Ferdinand von Richthofen (1877), and V. A. Obruchev (1894–96).

In the year 1920 Mr. Andrews submitted the plan to the president and trustees of the American Museum of Natural History, chiefly with the hope of putting to the test the theory advanced by the present writer in 1889 and 1890, that the high plateau region of central Asia would be found to be the chief homeland or centre of origin, evolution, and distribution of the great orders of mammals. With this main stated object and the discovery of the principal centre of human origin as the chief popular object, Mr. Andrews aroused widespread public interest and succeeded in financing the expedition for a five-year period, 1921–26. The first year, 1921, was devoted to organisation in China and Mongolia, to the assemblage of the scientific st and the *matériel* of the expedition. The second ye 1922, was given to a three-thousand-mile reconnaissan in the Gobi Desert and, for a short time, in the Khan Mountains north of the desert. The third year, 19 was given to intensive exploration in five of the m promising fossil-bearing formations discovered in 19

The 1922 party left Kalgan, northern China, April 20, according to programme, as follows: R Chapman Andrews, leader and zoologist; Wal Granger, chief palæontologist; Charles P. Berk chief geologist; Frederick K. Morris, assistant g logist and topographer; S. Bayard Colgate, mo expert in charge of three light and two heavy au mobiles; J. B. Shackelford, photographer. A ca caravan train of seventy-five cam left two months earlier and join the party in the centre of the G Desert. The entire personnel cluded twenty-three men—six Ame cans, eight Chinese, nine Mongolia By the perfect organisation a combination of the modern a more ancient methods of des transport, the party made a thr thousand-mile reconnaissance in t five months' season of 1922, to t north, to the north-west, south, a south-east, practically skirting t entire desert of Gobi east of t Altai Mountains, but leaving certa regions east of the Urga trail st unexplored.

Both the mechanical and t scientific plans of the expediti involved many hazards, becau automobiles had never previous been used in scientific explorati in Mongolia, and the accomplishment of the ma scientific purpose of the expedition by discovery the extinct fossil life of Mongolia and the remai of prehistoric man was at best extremely doubtf In all the early explorations, and even in more rece geological work, no land fossils had ever been foun with the exception of a single fragmentary rhin ceros jaw with two teeth, which was brought back b Obruchev.

The palæontological and geological results of t first year's reconnaissance were not only encouragi but also very surprising—in fact, they far exceed our fondest expectations. Only three days aft starting, the first bones of Baluchitherium were di covered in the Houldjin gravels, where Obruchev ha found the fragmentary rhinoceros jaw. A day late April 24, the rich dinosaur deposits of Iren Dabas 260 miles north of Kalgan, were located. On April 2 were discovered the rich upper Eocene titanothe zone of Irdin Manha and the Irdin Manha formatio by far the most extensive fossiliferous upper Eoce deposit known. The party journeyed north and wes the geologists recording a complete cross-section

the rock structures traversed and determining te geologic history of the region. The great bathylith r central Mongolia was determined by Berkey and rris in the traverse extending northward from algan and westward to the Altai Mountains. For is granitic mass, the dimensions of which seem to mpare favourably with the greatest bathyliths thus r known in other parts of the world, the name "the reat Mongolian Bathylith" is proposed. Above the thylith is found an unconformity, covering early alæozoic time; then a second unconformity between alæozoic and Mesozoic time; finally "the Great nconformity" which marks the close of Jurassic me.

From Jurassic time on, Mongolia has been continuously a continental surface, on which a series of more or less extensive *epicontinental* deposits were laid down. These epicontinental deposits extended in time from the base of the Cretaceous to the Pleistocene. The old rock floor which the bathylith invades includes deposits which range from the ancient Archæan gneisses to late Proterozoic graywackes and limestones which may well correspond with the Nan-K'ou series of von Richthofen. The epicontinental deposits above the old rock floor appear to correspond with the "Gobi Series" of Obruchev.

The technical, geological, and palæontological work of the expedition, largely accomplished in 1922, and continued and verified in 1923, was to analyse the "Gobi Series" of Obruchev into its component formations, beginning in lower Cretaceous time and extending to the close of the Tertiary. In every instance the geologist and topographer, and the four palæontologists worked together, and the rapid succession of important discoveries demonstrated over and over again the value of hand-in-hand work of highly trained field geologists and highly trained field palæontologists. The training of Prof. Berkey in the very difficult pre-Palæozoic and Palæozoic geology of the eastern United States was no less valuable than the quarter century of field experience in the deserts of western United States on the part of Mr. Granger and his able fossil-hunting assistants, Messrs. Kaisen, Olsen, and Johnson.

In the case of each of the three Cretaceous zones, only a single guiding fossil was found in the first season, namely, the skull of the primitive horned dinosaur Protoceratops and the skeletons of the two primitive iguanodonts, Protiguanodon and Psittacosaurus. The discovery of each of these guiding fossils required the sharpest vision and the most prolonged field training.

Fig. 2.—Members of the 1923 party of the Third Asiatic Expedition in camp at Irdin Manha. Middle row, left to right: Walter Granger, Prof. Henry Fairfield Osborn, Leader Roy Chapman Andrews, Frederick K. Morris, Peter Kaisen; top row (Americans), left to right: C. Vance Johnson, Albert F. Johnson, J. McKenzie Young, George Olsen. Two of the young Chinese members—Buckshot (front row, third from right) and Liu (top row, extreme right)—are now at the American Museum being trained as expert preparators. (Photograph by Walter Granger.)

Work during the season of 1923 on the Protoceratops zone proved it to be one of the richest and most remarkable dinosaur deposits of the world. It yielded seven clusters of the now famous dinosaur eggs, four of which were found *in situ*, apparently as they had been deposited, seventy-one skulls and several skeletons of Protoceratops, the ancestor of the great horned dinosaurs of Montana, and three new carnivorous dinosaurs, Velociraptor, Oviraptor, and Saurornithoides. This zone promises the complete life of mid-Cretaceous time in this hitherto unknown continent.

Altogether, eleven chief life zones were discovered in the season of 1922, and a twelfth zone in the season of 1923. In descending order these are as follows:

Pleistocene	OLAN and DISKE, containing *Elephas* and *Rhinocerus*, reported by J. G. Andersson.
Upper Pliocene	HUNG KUREH, 2000 feet, containing the stag *Cervus*, antelope *Hipparion*, camel, beaver, mastodon.
Miocene (?)	PANG KIANG, 500 feet, containing fragment of a rodent jaw, near *Ochotona*.
Lower Miocene	LOH, containing primitive mastodons related to those of the lower Miocene of France, and a rhinocerid.
Oligocene	HSANDA GOL, 3000 feet, containing the giant *Baluchitherium grangeri*, 19 genera of carnivora, rodentia, insectivora resembling those of France and the Rocky Mountains; also ancestral types of the cattle, deer, and pig family.
	HOULDJIN, containing *Baluchitherium*.
Lower Oligocene	ARDYN OBO, 500 feet, containing fauna similar to that of the Oligocene phosphorites beds of France—*Cadurcotherium*, *Schizotherium*, *Cynodictis*, *Eumeryz* (possible ancestor of the deer family).
Upper Eocene	SHARA MURUN, 300 feet, a mammal fauna resembling that of northern Wyoming and southern Dakota—*Protitanotherium* almost identical with species of northern Utah, long-limbed *Ceratherium*, and other mammals.
	IRDIN MANHA, 50 feet, vast flood plain rich in mammals closely resembling those of the upper Eocene of the Rocky Mountains, including carnivores, insectivores, numerous species of titanotheres, and great herds of a diminutive lophiodont. Here occurs the giant primitive carnivorous animal, *Andrewsarchos*, named after the leader of the expedition; also a new form of the dinocerata named *Eudinoceras*.
	ARSHANTO, at the base of the Irdin Manha, yielding numerous small lophiodonts.
Lower Eocene	GASHATO, 200 feet, apparently lower Eocene.
Upper Cretaceous	IREN DABASU, 150 feet, containing middle-sized *Iguanodon*, and the bird-mimicking dinosaurs.
	DJADOCHTA, 500 feet, life zone of *Protoceratops andrewsi*, a partly Æolian formation, 500 feet, containing rich primitive dinosaur fauna of *Protoceratops* and three types of small carnivorous dinosaurs; *Velociraptor*; *Oviraptor*, a small bird-like dinosaur found resting on top of a cluster of dinosaur eggs; and *Saurornithoides*. In this formation were found the seven clusters of eggs, comprising thirty-five well-preserved eggs altogether. In one cluster are seen what appear to be embryo skeletons, probably of *Protoceratops*. Thus all the growth stages in this primitive horned dinosaur, from the egg to the adult, constitute a series which gives us for the first time the ontogeny of a dinosaur.
Lower Cretaceous	ONDAI SAIR, 500 feet, containing *Protiguanodon mongoliense*, small leaf-eating dinosaur related to the *Hypsilophodon foxi* of the Wealden of England, also paper shales with insect fauna.
	OSHIH (Ashile), 1500 feet, containing small parrot-beaked iguanodont dinosaur known as *Psittacosaurus mongoliensis*, and the sauropod *Asiatosaurus* and theropod *Prodeinodon*.

In these *fifteen* formations, representing at least *twelve* new life zones, the main object of the Third Asiatic Expedition, namely, "to test the theory of the central Asian origin of the mammalian life of Europe and America," has been accomplished. According to Osborn's prediction of 1890, proof has been found of the existence in central Asia of all the great orders and of many families of mammals, excepti those orders which by common consent originat in South America, and the four orders which originat in Africa, namely, the proboscideans, the hyracoi the sirenians, and the toothed whales, according Osborn (1890) and the discoveries of Beadnell a C. W. Andrews (1893). Surpassing the verificati of this prediction as to the mammals, the centr Asian plateau proves also to have been the centre evolution and adaptive radiation of the great divisi of land reptiles known as dinosauria. From this gre home-country of land reptiles and of land mamma from Jurassic time onward, races migrated westwa to Europe and eastward to North America, and th affords the long-desired and complete explanation the community of the fauna of the Rocky Mounta region and of western Europe, in both Mesozoic a Cænozoic time.

It is a very significant fact in the history of pal ontology that the homeland of the mammals duri the Age of Mammals, and of the reptiles during t Age of Reptiles, is the very last to be discovere Beginning with the first palæontological work towa the close of the eighteenth century in Europe, co tinuing with the thorough exploration of Europe a southern Asia during the nineteenth century, and wi the wonderful discoveries in reptilian and mammali history in North America and South America fr the middle of the nineteenth century onward, t homeland was still left untouched and unexplore Discoveries in North America were so extensive a so revolutionary that many thought the homela had been revealed in our great western fossil be Positive claims were advanced by Ameghino Patagonia as the homeland of proboscidea and primat As a result of these discoveries in the western hen sphere, it proves true that several families of mamm did originate in North America and several orders mammals in South America, but the ancestral sto from which these orders radiated is to be traced the high plateau region of Asia, where similar cau prevailed first, in the origin of the terrestrial dinosau second, in the origin of the mammals; finally, may predict, in the origin of primitive man. The climatic and physiographic causes are an elevat country of the savannah type, largely open, part forested, in which there was throughout a seve competition and struggle for existence leading to high varied adaptive radiation.

The season of 1923 differed from that of 1922 in t intensive exploration of five of the chief formatio discovered, namely, Iren Dabasu, Irdin Manha, Sha Murun, Ardyn Obo, and Djadochta, yielding altogeth a great collection of fossils in a remarkable state preservation. These fossils were safely transport a thousand miles across the Gobi by camel carav in charge of Mongol drivers, and through superi technical methods reached the American Museu without the least injury. They are now being work out of the rock by a large force of men in the museu laboratories and are being described by Messrs. Osbor Matthew, Granger, and Gregory in a series of pr liminary papers in *American Museum Novitates* a in more popular form in *Natural History* and *As Magazine*. The perfect state of preservation of t

l bones and eggs, especially those from the Proto- tops zone, is without precedent; it appears as if l-driven sand suddenly overcame large numbers hese animals and buried the nests of dinosaur . Several of the Protoceratops skeletons were d entire; others were partly scattered. The little nal known as *Oviraptor philoceratops* (a name

Dr. Chaney, of the University of California, and an archæologist, Dr. Nelson, of the American Museum staff. The expedition throughout has enjoyed the hearty co-operation of the Geological Survey of China, which has contributed the services of one of its chief members, Dr. Amadeus Grabau, for the work in invertebrate palæontology and palæogeography. The

FIG. 3.—American Museum camp of the 1923 season on top of the lower Cretaceous formation Oshih (Ashile). Above is the Oshih plateau, which gives the region its name. Here were discovered the parrot-beaked iguanodont Psittacosaurus and the giant sauropod Asiatosaurus.

nifying "the egg-seizer with a preference for cera- psian egg diet") was found directly above one of e nests. This terrestrial dinosaur fauna is entirely new science because it belongs to a period known hitherto ly in scattered deposits of littoral formations.

Interest in these discoveries, particularly in the nosaur eggs, has been world-wide and makes evident constantly increasing knowledge of palæontology d anthropology, which is a most hopeful sign for e future. Upwards of ree thousand applica- ons have been received r places on the expedi- on. The original plan of e Third Asiatic Expedi- on was to terminate in 926 with excursions into nexplored portions of orthern Tibet and perhaps f Chinese Turkestan, but e discoveries in Mon- olia led to an import- nt change of plan. Under the very active leader- hip of Mr. Andrews a new scientific and financial ampaign, begun in November 1923, carried on in he chief cities of the United States, has resulted in a ow of contributions for the continuation of the expedi- ion over a new five-year period beginning in 1924. he sum of 254,000 dollars has all been contributed, nd subscriptions are coming from 235 individuals n twenty-five states. One of the leading automobile nanufacturers of America has designed new cars, specially adapted for desert work.

The expedition will return to Mongolia with the riginal personnel, strengthened by a palæobotanist,

FIG. 4.—Diagrammatic cross-section of geologic relations at Tsetsenwan. This section lies about 200 miles wes of Urga, where erosion had exposed the granite bathylith and carried away most of its roof of graywack before the Jurassic sediments were laid down. A synclinal remnant of Jurassic conglomerate is preserved here, although several thousand feet of these strata are to be found only a few miles away.

expedition has been favoured by the friendly co-operation of the Mongol Government at Urga, and it is expected that this support will be continued. After seven months of campaign work in America, Mr. Andrews has returned to Peking and will outfit a caravan of two hundred camels to leave Kalgan in December so as to reach the future base of the expedition in western Mongolia in the month of May 1925. From this base, explorations will extend northward and south-westward, carrying the reconnaissance of 1922 into regions not previously explored. The upper Tertiary deposits will, in the meantime, be very carefully explored to test the new theory advanced by Osborn that we must look in the high plateau of Asia or of Europe for the Tertiary ancestors of man. The final publications of the Expedition will appear in a series of volumes entitled "Mongolia and China," of which volume i. will be the narrative of the expedition by Andrews. Volume ii., which will contain the observations and researches of Messrs. Berkey and Morris on the geology and topography, is now in preparation.

The Forces which lift Aeroplanes.[1]

By Prof. V. K. F. Bjerknes, Geophysical Institute, Bergen.

The Direct Geometric Analogy.

THE fields of motion produced by the pulsating and the oscillating bodies are traced out by the registering instrument, and they can then be compared with the corresponding magnetic fields shown, for example, by iron filings. In this way it can be demonstrated that there is the most striking correspondence between the geometric structure of the hydrodynamic and the magnetic field (Fig. 2). The finest part of this geometric analogy, however, which concerns the simultaneously existing impressed and induced fields in the internal spaces, can only be recognised mathematically. There is the same striking resemblance between the hydrodynamic fields of permanent motion, and the corresponding magnetic fields of steady electric currents.

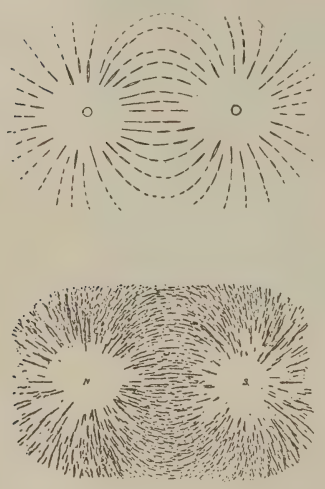

Fig. 2. — Example of the geometric analogy: bodies pulsating in opposite phases and magnetic poles of opposite signs.

One important reservation should be made, however, in connexion with this and the following experiments concerning permanent motion. The theory assumes a frictionless fluid while we make use of the fluid friction as a practical means for producing the required permanent circulation. We have brought in thereby an element not completely contained within our theory: this is important in order that we may recognise later the proper limitations of the conclusion derived from our theory.

The Inverse Dynamic Analogy.

We can also examine the mechanical forces in the two different kinds of field, and it is found that the hydrodynamic force produces attractions, repulsions, lateral displacements, and rotations equal but opposite to those which the corresponding magnetic force produces.

The analogy may be pursued in the most minute details. In all cases we have attraction by oscillations which are symmetrical, and repulsion by oscillations which are anti-symmetrical with respect to a plane, just as in magnetism we have attraction in the case of symmetry and repulsion in the case of anti-symmetry.

Passing on now from the analogy concerning vibratory motion to that of permanent motion, two cylinders rotating in the same direction repel each other so soon as they have had time to produce by friction the required circulating motion of the water. This corresponds to the attraction between electric currents in the same direction. Changing the direction of rotation of one cylinder, the repulsion changes into attraction as soon as the new motion has had ti to develop itself. This corresponds to the repulsi between anti-parallel electric currents.

Theoretical Aeroplane.

When my father had shown his experiments he w often asked if he could not imagine practical applic tions of them. He always answered, "That is n my affair." But if then the inquirer, half excusi his question, added, "The forces are perhaps too feel to be of any use," he always got the answer, "Fro that point of view there is no objection. There is limit to the strength of the forces."

Returning to this question now, forty to fifty yea later, we at once see an application of the last illustr tion, namely, that with the rotating cylinders. T experiment succeeds equally well in air and wat The force will be reduced in proportion to the densit but for this we can compensate by increasing the spe of rotation. One cylinder is displaced normally to t wind produced by the other, or normally to a wi produced by any means, just as an electric current displaced normally to a magnetic field however the fie may be produced: the rotating cylinder is displac towards that side where the circulation round it assis the external wind, while the current is displaced towar that side where its own field opposes the extern field.

We can then use our rotating cylinder to ascend the air. Given a horizontal wind, let the cylinder l placed horizontally and normally to the wind ar rotated so that on its under side it moves against ar on its upper side with the wind. Provided we preve it from being carried along with the wind, it will th be pushed upwards as if attracted by an opposite rotating cylinder higher up. Using the analogy v may calculate the force per unit length of the cylinde To avoid unnecessary complications we use Heaviside rational electromagnetic units. Then the hydr electric current i equals the line-integral of the hydr magnetic force, *i.e.* of the specific momentum, along closed curve round the cylinder. Taking the consta density ρ of the air outside the integral sign we g $i=\rho\Gamma$, Γ representing the circulation round the cylinde And multiplying by the hydro-magnetic induction, i. the velocity v of the wind, we get the force per un length of the cylinder:

$$F=iv=\rho\Gamma v.$$

The formula will be exact if for Γ we take the circul tion actually produced in the free air. But not know ing this circulation we may try as a first approximatio to identify it with that of the circumference of th cylinder, fully recognising that we do not know to wha extent friction is able to transfer this circulation to th air. Let then the cylinder have a periphery of metre and a circumferential velocity of 1 metre pe second. This will give unit circulation in the metre ton-second system. If, further, the wind has th strength of one metre per second, and if we put th density of the air for simplicity equal to 1/1000, we hav

[1] Continued from p. 474.

each metre of the cylinder the lifting force of

$\frac{1}{1000}$ M.T.S. force units $= \frac{1}{10}$ kilogram.

cylinder of ten metres length will then carry a kilogram. If we increase the circumferential velocity from 1 to 10 m. per second, the cylinder will carry 10 kg. If then we increase the wind velocity from 1 to 10 metres per second, it will carry 100 kg. Retaining the angular velocity and increasing the circumference of the cylinder from 1 to 10 metres, we get a lift of 100 kg., and so on.

Instead of letting the cylinder mount in the wind we can move it against the resting air. We then get an aeroplane having a rotating cylinder instead of the aeroplane wings, and as our calculations have shown, it should be a very effective aeroplane from the point of view of lift if only a small fraction, such as the half or even the fifth part of the circulation of the cylinder, be transferred effectively to the air. But only experiments can give full information of this effectiveness.

The technical difficulties of such an aeroplane, however, are obvious. The main interest is, and will probably remain, theoretical: it is a mental instrument illustrating the dependency of flying upon the hydrodynamic actions-at-a-distance, just as Carnot's thermodynamic engine illustrates the dependency of the steam-engine upon the second law of thermodynamics. To see the relation of this, theoretically the simplest aeroplane, to the real aeroplane we must go to the results obtained by experimental work in the aerodynamic laboratories.

Automatic Production of the Lifting Circulation.

Here we meet with effects of friction which are not contained in the theory developed. We started with the paradoxical result that a spherical body moving in uniform velocity through a frictionless fluid experiences no resistance according to the solution of the hydrodynamical equations. What is then the origin of the resistance always experienced, which seems to be far too great to be explained merely as a direct effect of the small viscosity? The general reason has long been known: it is the formation of a wake of eddies. The origin of these vortices has been investigated especially by Prandtl and his school in the aerodynamical laboratory in Göttingen.

As demanded by theory, the vortices never originate in the free fluid. But however small the viscosity of the fluid may be, there will always be a thin layer close to the surface of the body in which the fluid masses are subject to an intensive shearing effect. This disturbs the symmetry of the motion which should otherwise exist between the front and the back of the cylinder (fig. 3). Retarded fluid masses gradually accumulate behind the cylinder, forming there two vortices. From time to time these vortices are carried away, alternately from each side, producing the eddying wake (Kármán's experiment). The resistance experienced by the cylinder is due to the work done in forming these eddies.

Now let us replace the circular cylinder by an elliptic one, set obliquely to the current. The symmetry being lost, the leeward and the windward vortices are formed under different conditions, and more especially, the conditions for their discharge are different. The windward vortex is carried away with the current, while the leeward remains anchored to the cylinder, forming a circulation round it. The lifting effect upon the inclined plane comes exclusively as a consequence of the circulation thus formed round it—a fundamental fact in aerodynamics first recognised by Lanchester, and put into a formula by Kutta and Joukowski. This formula is the same as that which we have just deduced from the hydrodynamic analogy to the electromagnetic field, and, as seen from this analogy, it is valid for all cross-sections of the wings and for circulations of any origin, not merely for the circular cross-section of the rotating cylinders in our theoretical aeroplane.

The difference between our theoretical aeroplane with its rotating cylinder and the practical aeroplane with its inclined wings reduces to this: with the rotating cylinder we produce systematically, in a way which

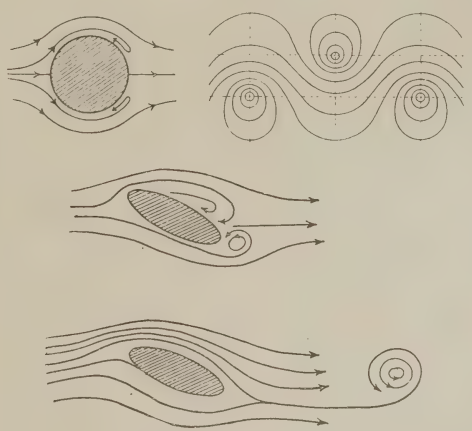

Fig. 3.—Different cylinders in a current.

we can control, the circulating motion which is the condition for lift. By the ordinary aeroplane wings the lifting circulation is produced spontaneously by the asymmetry of the wing.

Induced Resistance.

From the hydrodynamic analogy we have deduced the force lifting an aeroplane. In addition to the lifting force the aeroplane is subject also to head-resistance of which the analogy gives us the theory. Every vortex which the aeroplane leaves behind in the air represents a hydro-electric current which exerts its action-at-a-distance upon that main hydro-electric current which carries the aeroplane.

Fig. 4 shows diagrammatically the system of vortices which every aeroplane must necessarily leave behind itself: namely, the windward vortex which at the moment of starting is carried away from the aeroplane, and the vortices with axes parallel to the wind which join the ends of this vortex with those of the leeward vortex that remains anchored to the wing and carries the aeroplane. This gives a closed vortex having the form of a rectangle of which two sides are constant in length, while two increase with the velocity of the aeroplane relatively to the wind. What the aeronautical engineers call the induced resistance may be regarded

as the hydro-electric attraction of that part of the vortex system which is left behind in the free air upon that part which is anchored to the wing. The analogy with electromagnetism allows us immediately to write down formulæ for this attraction.

The theory of hydrodynamic actions-at-a-distance, which has hitherto been so absolutely useless from a

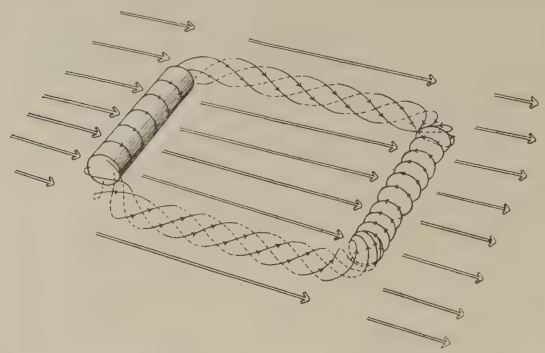

FIG. 4.—Vortex system set up by an aeroplane.

practical point of view, has recently become very practical. It opens up the possibility of applying electromagnetic formulæ to the theory of aeroplanes.

Moreover, it is a short step from the theory of the wing to the theory of the propeller. The fact that its motion is circular instead of translational is of no importance. The force exerted against the propeller blade depends upon the circulation produced round and can be calculated by the theory of the hyd dynamic actions-at-a-distance. From the prope blade the way is not far to the turbine blade. T type of driving force will remain the same whether t driving medium be incompressible water or expandi steam. In the latter medium, effects of expansion v come into play of the kind exemplified by the expe ment with the pulsating bodies. But the greater t complications, the more complete is the use which h to be made of the theory of the hydrodynamic actio at-a-distance.

It is not least interesting from this point of view consider the transfer of mechanical to electrical ener or vice versa. Let us suppose that at one end of shaft we have a water or steam turbine, at the other e a dynamo. At the turbine blades the hydrodynan actions-at-a-distance are in activity, and in the dyna the equal but opposite electromagnetic actions. W derive both of them by the same formulæ, only wi a change of sign when we pass from one set to the oth One set of forces is like a reflected image of the othe

Do we not here behold a deep harmony of Nature a point where important practical problems are int twined with ideas of deep theoretical interest? Final what does Nature mean by placing us face to fa with this wonderful harmony between such differe branches of physics as hydrodynamics and electr dynamics? This is a question which may be answer by a future Faraday.

Obituary.

VISCOUNT LONG OF WRAXALL, F.R.S.

LORD LONG of Wraxall, whose death occurred on September 26 at seventy years of age, was well known to British workers in several scientific fields. He will be particularly remembered for the unswerving support which he gave to scientific advisors while president of the Board of Agriculture in 1892–1900, as regards the necessary measures to extirpate rabies from the British Isles. At that time it had been proved beyond doubt that hydrophobia was a specific infective disease which did not originate *de novo*, but could only be introduced into a district or country by being passed on from animal to animal. Acting upon this and other knowledge when president of the Board of Agriculture, Lord Long was responsible for the issuing of muzzling orders for dogs, first for London and then for the whole country. The National Canine Defence League thereupon instituted a public campaign against the muzzle and condemned the measures wisely adopted by the Board. Lord Long, however, had instructed himself thoroughly well in the whole question of rabies, and, with laudable firmness, he resisted the outcry and the repeated assaults of the uninstructed sentimentalists. As a result, he was able to demonstrate that, by the strict carrying-out of muzzling orders, rabies could not only be checked but also reduced eventually to extinction. The eighty thousand "dog-lovers" who petitioned for Lord Long's dismissal from his office at the Board of Agriculture showed themselves to be poor friends of dogs by their action, which many of them must afterwards have regretted. In recognition of his work on behalf of science, Lord Long was elected a fellow of the Royal Society in 1902. He was also an honorary LL.D. of the University of Birmingham.

DR. R. S. WOODWARD.

DR. ROBERT SIMPSON WOODWARD, formerly preside of the Carnegie Institution of Washington, died June 29, aged seventy-four, and the following accou of his scientific work is taken from the Journal of t Washington Academy of Sciences. Dr. Woodward w born at Rochester, Michigan, July 21, 1849. Followi his education as a civil engineer at the University Michigan, he served with the U.S. Lake Survey, t Transit of Venus Commission of 1882, the U.S. Ge logical Survey, and finally the U.S. Coast and Geodet Survey. Leaving the Federal service in 1893, he b came professor of mechanics and mathematical physi at Columbia University, New York City. In 1905 succeeded the late Daniel Coit Gilman as president the Carnegie Institution of Washington, then but r cently founded by Andrew Carnegie. Dr. Gilman term of office as its first president had been very sho and the real responsibility for formulating the worki plans for the development of a new and comparative untried form of research institution fell upon D Woodward. Following fifteen years of successful a ministration in this office he retired from active du in January 1921. He was president in 1900 of t American Association for the Advancement of Scien and had also served as president of the America Mathematical Society, the Washington Academy Sciences, and the Philosophical Society of Washingto He was a member of the National Academy an other national organisations. Dr. Woodward mad notable contributions to mathematical physics an astronomy, especially as applied to geodesy an geophysics.

Current Topics and Events.

On September 27 Ivan Petrovich Pavlov, the great Russian physiologist, celebrated his seventy-fifth birthday, and it is gratifying to learn that he is still in the full force of his mental power and physically strong, working hard at various physiological problems. His birthday is indeed an international event. Prof. Pavlov's scientific work can be divided clearly into three periods: study of the heart and blood circulation (1877–1890), investigations on the digestive system (1890 until about 1905), and research on the physiology of the brain (the last period). This distinctness in the division of his life was made consciously and is not accidental. The present writer remembers a conversation in Prof. Pavlov's laboratory during tea time, when methods of increasing the productiveness of scientific workers were being discussed. After different ideas had been suggested by his pupils, Pavlov smiled and said, "Well, from my experience, the problem seems very simple, although hard to perform. There is only one method; concentrate all the powers of your soul and body on one idea, which you investigate. Stick to it for many years, think of it daily and dream about it during your sleep. That's all." The results of Prof. Pavlov's work in the three departments of physiology he has studied are brilliant. He has discovered many important facts in the physiology of the heart and circulation of the blood, chiefly concerning the vago-sympathetic innervation of the cardio-vascular system. His investigations on the physiology of the digestive processes have changed completely our ideas on this subject. The secretory innervation of the stomach and pancreas, and the discovery of the laws governing the secretion of the digestive juices by the use of fistulas, are the most important results of his and his pupils' work. Finally, Pavlov crowns a long life, which has been devoted to science, by investigating the physiology of the brain. He is now in the course of writing a book summarising the great results of this work, which he has obtained by means of a simple but ingenious method of conditional reflexes. For Russia, Pavlov is especially precious not only as a scientific worker of great distinction but also as an example to young Russia at the present time. During 1920 and 1921 he and his family suffered badly from lack of food. He was obliged to spend valuable time in domestic work and in searching for food and fuel. In spite of this, Pavlov continued his work, at that time in unheated laboratories, hungry himself with hungry pupils, giving an example of a truly great man, who lives for one thing only—the pursuit of truth.

The retirement of Prof. F. O. Bower from the Regius chair of botany in the University of Glasgow reminds us of the remarkable developments for both teaching and research which have marked the past forty years. During the long tenure of his chair, Prof. Bower has taken a conspicuous part in raising the standard of biological teaching and research in British universities to the high position which it holds to-day. The beautiful laboratories erected in Glasgow under his direction were indeed the material expression of the ideals born during his earlier associations with such men as Sachs, Vines, and Marshall Ward. In those days it was almost a belief that many of the manifestations of life which the microscope had revealed could be observed only in German laboratories. The removal of such views liberated botanical inquiry in Great Britain from the narrow courses of pure systematics. The widespread enthusiasm for biological investigation along lines not yet explored left their deep impression on a highly responsive mind and gave us a man of vigorous frame whose enthusiasm for the problems of plant-structure was coupled with a conspicuous power of exposition.

It may not be widely known that Prof. Bower was among the first of living botanists to deliver a course in botanical physiology in Britain. His investigations into those problems of structure and affinity of Pteridophytic plants, and their presentation in a long series of memoirs, are widely known and appreciated. It has been a pleasure to those who have known Prof. Bower at work to see his reliance on such simple apparatus and laboratory methods as have been the bare essentials to his investigations. As a teacher he will be long remembered. An army of enthusiastic students of medicine has passed under his influence in the University of Glasgow. Their instruction in the broad principles of life as illustrated by the plant-kingdom has been to him a peculiar responsibility and pleasure. As a teacher of advanced students he displayed those high qualities of presentation and a love of argument and reasoning which have so fully marked his scientific writings. To the retirement which Prof. Bower is now seeking he will carry not only the highest appreciation of those who have been privileged to work with him and to know him, but also of the many who have been quickened by the great philosophical considerations regarding the problems of life which have been the mainspring of his work.

After twenty-four years' work, Mr. Ling Roth, who is in his seventieth year, has resigned the keepership of Bankfield Museum, Halifax, owing to ill-health. Acting on the fact that Halifax is a textile manufacturing town surrounded by towns carrying on various branches of the textile industry, Mr. Ling Roth judged that an historical collection of textile tools might be useful, educational, and interesting to the town; and he has succeeded in gathering together a fascinating assembly of specimens of primitive textile tools from many parts of the world. The grouping begins with a selection of basketry followed by samples of matwork, including mat looms in which the filaments are not spun. Then follows a series of implements for spinning with spindle only, spindle and distaff and hand-spinning machines, ending up with an old local wooden hand-spinning jenny which was in use so late as 1916. The collection of hand looms

and rug looms is large and varied both in character and origin and includes two recently acquired and so far undescribed braid looms from China. There is also a considerable series of spools and shuttles, with a set showing the process of manufacture, and one wall case with specimens illustrating the development of the shuttle. From plain cloths we come to patterned cloths and embroideries, and finally there is a collection of the embroidery tools used by ladies of the eighteenth and nineteenth centuries and a rare selection of ladies' work-boxes and their muneries and often exquisite fittings or tools. The whole forms a unique collection such as exists nowhere in any other museum, and gives the visitor or student a clear survey of the tools used in the industry from its very beginnings up to the period when power spinning and weaving came into being.

MR. J. C. MOUTTON, of the Residency, Kuching, Sarawak, directs our attention to a "General Report on the Fisheries of British Malaya," published at the Government Printing Office in Singapore, in 1923. There Mr. David G. Stead writes: "In making this essential appointment [Superintendent of Fisheries Investigation in Malaya] I recommend the Government to give the fullest encouragement to the great College of Fisheries of Seattle, Washington (United States of America), or to the Stanford University of California, to offer a candidate for the position. . . . If only a marine biologist had been wanted I would have unhesitatingly recommended to the Government to make an appointment from amongst the scions of one or other of the universities of Great Britain—but however good may be (and undoubtedly is) the training given in biological work in these institutions, there are none of them, unfortunately, specialising to any great extent in applied fishery work." Now an institution that trains investigators can only become "great" and well known by reason of the work done by its past students, and the College of Fisheries at Seattle, Washington, U.S.A., has still to become famous, judged in this way. It is, in fact, only a few years old. Thus a comparison with the British university training schools cannot be made. But, for any work in fishery investigation, the essential training is that in marine biology and oceanography. That can be obtained at Liverpool or Cambridge, and at the Plymouth or Port Erin Biological Stations, in a perfectly satisfactory manner.

IT is true, as Mr. Stead suggests, that no British university has a Fisheries College attached to it, but those with experience of what fishery investigation involves know that this kind of training can best be obtained, by actual post-graduate work, at the Marine Biological Stations, at the official fishery laboratories, and at sea with the fishery investigation vessels. All these opportunities exist and are used in the training of fishery workers. The ordinary period of time required for an honours degree in marine biology and oceanography is certainly not too long for a really useful knowledge of those subjects, and the man who intends to superintend fishery investigations ought to have this knowledge, as well as practical experience of the special methods of research and of the actual conditions of the fishing industry. At present t training can be obtained at British universities, biological and fishery laboratories, by actual cont with the industry at the fishing ports, and on boa fishing vessels. It can probably be so obtain better than anywhere else in the world, and it is t kind of preparation for investigation of fish problems that is expected by Government depa ments concerned with the administration of t industry.

THE Western Union Telegraph Company has lit fear that the new developments in radio communic tion will seriously affect the traffic by submari cable. The Company has just completed laying a cat between New York and the Azores, a distance 2400 miles. It was manufactured and laid by t Telegraph Construction and Maintenance Compa of London. It is interesting to remember that t Company laid the original Atlantic cable. The ne cable marks an epoch in the development of su marine signalling. To borrow a "telephone" phra it is "uniformly loaded" with a band of that high magnetic material called by the Western Electr Company, which first introduced it to enginee "permalloy." It is an alloy of nickel and iro This band enables signals to be sent six times quick than with an ordinary cable. It is expected th 1500 letters a minute will be transmitted when t cable is in full working order. It is to be used wi an ordinary cable made by an Italian compa which will connect the Azores with Italy. When th is completed, submarine communication betwe Southern Europe and North America will be esta lished for the first time.

WE learn from the Paris correspondent of *T Engineer* that the decree authorising a French gover ment concession for the construction of a tidal pow generating station at Aber Vrac'h, near Brest, to t cost of which the State will contribute in a lar proportion, has been published. While the Ab Vrac'h scheme is mainly experimental, it is intend to pay its own way and will provide Brest with curre by a high-tension main of 30,000 volts, and to ensu a regularity of supply the tidal power plant will wo in conjunction with a power station utilising a hea of water provided by a barrage across the mouth the river Diouris. The Aber Vrac'h barrage will b 150 m. long and from 12 m. to 24 m. wide, and wi be composed of three concrete caissons containing th reversible turbines and alternators. A sluice ga will permit of the basin above the barrage being fille by the rising tide. The turbines will run from nin to eleven hours each tide. Spare chambers are to b reserved in the barrage for carrying out experiment with different kinds of turbines, with the idea attacking any problems that appear to present diffi culties in the utilisation of tidal power. The powe station will not ensure an uninterrupted supply o current; this will be provided for by the Diouri river barrage with a head of from 8 m. to 24 m. an actuating four turbines, each of which will develo from 75 horse-power to 1200 horse-power accordin to the tides.

RCHÆOLOGISTS and others who are interested in h history and topography of Great Britain will ve come the admirable map of Roman Britain which as been issued by the Ordnance Survey (price 4*s*.). e scale is 16 miles to the inch. The map shows the ncipal settlements both military and civil, but not gle villas, though a contingent promise is made that is may be included in a later issue. The roads shown re those constructed by the Romans, the trackways hich belong to an earlier system, such as the Icknield Vay, being omitted. The names in use in later times —Vatling Street, the Fossway, and Akeman Street, re the like, for which there is no evidence before the Saxon invasion—are also not shown. This is perhaps one regretted on the ground of their general famil- iarity. Where the course of a road is known with certainty from direct evidence, it is shown by a continuous double line; where it is uncertain, by a broken double line. Roads known to have existed, but for the course of which there is no evidence, are omitted. Modern names are written in italics; ancient names (when known) in Roman capitals. No attempt has been made to restore the coast line, which is known to have differed considerably on the south and east in Roman times, but the existing coast line has been shown.

THE International Commission of Eugenics held its annual meeting in Milan on September 20–22, repre- sentatives from Norway, Holland, Belgium, France, Russia, and Italy being present. The proceedings related chiefly to business matters, to international co-operation with other bodies, and to the publica- tion in Italy of an international "Bibliothèque d'Eugénique" by the Bureau of the Società per Previdenza ed Assistenza Sociale under the auspices of the Italian society. At the same time, the first Italian Congress of Social Hygiene and Eugenics was being held in Milan, at which Major Leonard Darwin, president of the Commission, read a paper on the "Criminal from the Point of View of Eugenics." An interesting feature of this meeting was the presence of the Rev. Prof. Agostino Gemelli, rector of the Catholic University of Milan, who read an interesting paper on Eugenics and intervened in debate with interesting reports of researches in heredity. Birth-control figured largely, probably for the first time in Italy. At the inaugural meeting it was announced that a chair in social eugenics was now to be founded in the new University of Milan, and at the closing banquet a munificent endowment for the same was announced. Prof. S. Patellani, general secretary to the congress, will be the first occupant of the chair.

THE American aviators, leaving Boston on September 8, have completed their voyage of circum- navigation by their arrival at Seattle on September 28, just under six months from the official start on April 8. The crossing of the United States was of the nature of a triumphal procession rather than a serious test of the possibilities of air transport, as might be inferred from the time taken. The only serious topographical obstacle was that presented by the Rocky Mountains.

THE Department of Agriculture of the Irish Free State is requiring an assistant plant pathologist. Candidates must hold the Associateship of the College of Science, Dublin, or a University degree in science, including botany. Applications should reach the Secretary of the Department, Upper Merrion Street, Dublin, by, at latest, October 9.

THE second session of the Liverpool Psychological Society will commence on October 7, when the president, Dr. Betts Taplin, will deliver his inaugural address at the University at 8 P.M. on "The Power of Suggestion." The Society's first session was very successful, and an interesting programme of scientific research has been arranged for the coming winter. Further particulars may be obtained from the Secretary, The University, Liverpool.

APPLICATIONS are invited by the Ministry of Agriculture and Fisheries for the post of an inspector in connexion with agricultural and horticultural edu- cation and research. Candidates must have taken a course in science or agriculture at a university or college of agriculture and had special training in the science and practice of poultry and small livestock keeping, including goats and rabbits. The necessary form of application (returnable not later than October 20) may be had from the Secretary of the Ministry, 10 Whitehall Place, S.W.1.

THE South African Institute for Medical Research, Johannesburg, is undertaking a research into the harbouring of plague by wild rodents, and the specific prophylaxis and therapy of the disease in man. In connexion with the inquiry, applications are invited for the posts of a bacteriologist and an entomologist. The former should preferably be a medical man with special experience of plague; the latter not necessarily a medical man, but, if possible, with special experi- ence in the study of ectoparasites of rodents. Further particulars can be obtained from "Bacteria," c/o the Director, Lister Institute, Chelsea Gardens, S.W.1.

MR. J. W. HAYWARD sends us an account of an unusual display of lightning which he observed in the neighbourhood of Lake Superior, Quebec, on August 31 last. The lightning took the form of an orange- coloured spark the size of a bright star which traced a narrower and whiter irregular line in a horizontal direction across the sky. Just before disappearing, the head of the flash divided into three or four parts which traced out divergent paths. The motion was sufficiently slow to be followed by the eye, and the whole path with its diverging ends remained visible for an instant. This is apparently a case of rocket lightning, an example of which was described by Mr. W. H. Everett in NATURE of October 22, 1903, p. 599.

THE Council of the Institution of Civil Engineers has made the following awards in respect of selected engineering papers published without discussion dur- ing the session 1923–1924: A Telford Gold Medal to Mr. E. H. Lamb (London); and Telford Premiums to Messrs. F. C. Temple (Jamshedpur, India), H. A. Lewis-Dale (London), and Mr. C. J. Gyde (Pretoria). And in respect of papers read at students' meetings in

London, or by students before meetings of local associations during the same period: The James Forrest Medal, the James Prescott Joule Medal, and a Miller Prize to Mr. R. W. Mountain (London); and Miller Prizes to Messrs. H. S. Smith (London) and C. D. Crosthwaite (London), H. C. Toy (Birmingham), F. W. S. Hawtayne (London), E. G. Wilson (North Shields), and W. W. Davies (London).

THE various types of microscopes manufactured by Messrs. C. Baker, of 244 High Holborn, London, W.C., are described and illustrated in a recently issued edition of this firm's catalogue. Instruments suitable for use in biological, metallurgical, and mineralogical work are included, as well as simpler models for science students. With the view of obtaining greater facility of adjustment or increased rigidity or efficiency, modifications have been introduced in several of the firm's well-known models, and standardisation of parts has been effected wherever possible. Full details are given of all necessary optical equipment, including a series of orthochromatic eyepieces recently designed by Lt.-Col. Gifford to give an increased field. A very complete list of mechanical accessories and illuminating apparatus is also given. Amongst the photomicrographic apparatus may be mentioned the Universal Geometric Slide Camera, designed by M J. E. Barnard. In the design of this apparatus t geometric principle has been observed throughou with the result that extreme rigidity can be obtaine and relative movement of any parts avoided wh the apparatus is subjected to vibration.

MESSRS. Percy Lund, Humphries and Co., Lt hope to publish in December the Transactions, four volumes, of the recently held World Power Co ference. The work will include all the papers pr sented at the conference, and contain a synopsis the discussions which followed the presentation the papers. Most of the papers will be illustrated maps, charts, diagrams, and reproductions of phot graphs.

WE learn from Messrs. Adam Hilger, Ltd., 7 Camden Road, London, N.W.1, that the firm h been entrusted with the manufacture of the inte ferometric apparatus with which the metre will established in Japan, in accordance with the la passed in March 1921 by the Japanese Diet maki the metric system compulsory in that country. T apparatus will also provide for the measurement the 5-metre base, which is the foundation of t geodetic survey in Japan.

Our Astronomical Column.

FINSLER'S COMET, 1924 *c*.—This comet has been well observed, and was of at least the fifth magnitude on September 22, when it was visible in considerable twilight. Dr. W. H. Steavenson traced the tail to a length of 15′. The following elements, by J. P. Möller and B. Strömgren, from observations on September 21, 22, 23, are near the truth.

$T = 1924$, Sept. 4·559 G.M.T.
$\omega = 66^\circ\ 26{\cdot}5'$
$\Omega = 79\ \ 5{\cdot}8$ } 1924·0
$i = 121\ \ 59{\cdot}8$
$\log q = 9{\cdot}61047$

EPHEMERIS FOR GREENWICH MIDNIGHT.

		R.A.	S. Decl.	$\log r$.	$\log \Delta$.
Oct.	6.	$15^h\ 12^m\ 6^s$	$7^\circ\ 51'$	9·9446	0·1688
,,	10.	15 22 12	10 39	9·9804	0·2033
,,	14.	15 31 0	13 2	0·0132	0·2347
,,	18.	15 38 36	15 6	0·0433	0·2633

The comet will be difficult to observe, being in the evening twilight, and low down. It is, moreover, fading rapidly.

RELATIVE NUMBERS OF STARS OF DIFFERENT SPECTRAL TYPES.—Many valuable papers on stellar statistics have been published. One of the latest is by K. G. Malmquist (K. Svenska vetenskaps. Handlinger, 3rd series, Band 1, No. 2) on the distribution of absolute magnitudes. The author adopts as his unit of distance the siriometer, which is a million astronomical units, or 4·85 parsecs. He gives as the number of stars of each type in a cubic siriometer in the neighbourhood of the sun:—B 0·005, A 0·033, F 0·300, G (giant) 0·006, (dwarf) 0·830, K (giant) 0·045, (dwarf) 2·100, M (giant) 0·004, (dwarf) more than 2·400; total 5·723.

The table brings out in a striking manner the vast excess of dwarfs over giants. The actual excess is probably much higher than the above figures indicate. Thus, Malmquist gives some 24,000 stars within 10 siriometers of the sun, of which 1 is of absolute magnitude −4, 7 of −3, the number per magnitude increasing to about 4000 in the neighbourhood mag. 8, and then falling off to 30 for mag. 12. Th falling off is probably only apparent, and due to t manner of selection of the stars he used, as a stud of the sun's nearest neighbours suggests that t absolutely faint stars are far more numerous.

It is to be hoped that a decision will be mad between the siriometer and the parsec as units stellar distance. The use of two different system causes needless confusion.

ORBITS OF COMETS.—A Copenhagen circular giv the following elements of Comet 1924 *a* (Reid) fro observations made at the Cape in March, April, Ma

$T = 1924$ March 13·290 G.M.T.
$\omega = 271^\circ\ 20'{\cdot}19$
$\Omega = 113\ \ 59\ {\cdot}57$ } 1924·0.
$i = 72\ \ 20\ {\cdot}36$
$\log q = 0{\cdot}24432$.

An ephemeris is given for September, the estimate magnitude being 10. But as no observation reported, it is probably fainter than this.

Prof. A. Dubiago, of Kasan, gives in *Astr. Nach* 5311 the following elliptical elements of the come 1921 I, discovered by him.

$T = 1921$ May 4·87982 G.M.T.
$\omega = 97^\circ\ 26'\ 32''{\cdot}2$
$\Omega = 65\ \ 59\ \ 8\ {\cdot}8$ } 1921·0.
$i = 22\ \ 21\ \ 20\ {\cdot}0$
$\log q = 0{\cdot}048102$.
$e = 0{\cdot}939585$.
$\log a = 1{\cdot}266949$.
Period, 79·50 years.

The comet was observed from April 24 until Jun 11, 1921, at eleven observatories. It was ill-defined and the probable errors of the observations ar large, but a parabolic orbit appears to be definitely excluded.

The comet is an eighth member of Neptune' family. Five of them, including Halley's, have bee seen at more than one apparition.

Research Items.

Early Christian Legends in India.—Father ...ten, in a contribution to the history of pre-...tuguese Christianity which is published as No. 5 of ... xix., N.S., of the Journal of the Asiatic Society of Bengal, discusses the origin of a number of the ...nds which centre around St. Thomas, his ministra-... and martyrdom in India, and his connexion with ...apore (Malabar). A Latin hymn, dating possibly ...the fourteenth century, refers to the conversion ...the saint of three kings, and goes on to say that ...eretic, pagan, or Jew could live in the city where ... body lay, and that on his feast-day he appears ... administers the sacrament to the faithful, with-...cling it from the unfaithful. The origin of these ...rences is found in the stories said to have been ... at Rome about A.D. 1122 by one Mar John, who ...escribed as Patriarch of the Indies. A descrip-... of the saint's feast by Theodore, *circa* 590, ...orded by Gregory of Tours, compares closely with ...ditions which prevail during feasts in Hindu ...nes and temples. A number of legends are told ...he miraculous attributes and actions of the right ... of St. Thomas. One of the most remarkable ...allels, which must be due to borrowing on one side ...the other, is found in a Mohammedan story ...ting to the Moslem saint Tamim from Covalong, ...r Mylapore, which follows the story of the burial ...St. Thomas in all its main details. The corre-...ndence may be due to an early conversion of ...abar Christians to Islam.

Egyptian Affinities in Indian Funerary Practices.—Dr. Govind S. Ghurye has collected ...ether and published in *Anthropos*, vol. xviii.-xix., ...umber of examples of funerary ritual among the ...ples of India which, in his opinion, even among ...se who practise cremation, point to affinities with ...practices of Ancient Egypt. Among the Nayadis, ...urn in which the calcined bones are buried is filled ...th curds and honey, and butter, sesamum, and ...ley are placed in the burial pit with it. The ...tom of anointing the body with oil, turmeric, or ...r substances, and the use of a new cloth to cover ...before burial or cremation, point to a survival of ...idea of embalming. The Egyptian life-like por-...t of the deceased survives, in accordance with ...principle suggested by Elliot Smith, in the stone ...s in connexion with the rite of cremation, which is ...rded among the higher castes for some time as the ...ge of the dead, and among the lower castes ...erally in an effigy of the dead made of earth, ashes, ... other material. Further, the Proto-Egyptian ...tice of protecting the corpse from the soil by mats, ...t-skin, or other means, and the pre-dynastic "pit ...ve" with its shaft and recessed chamber, each find ...allels in Indian custom. Dr. Ghurye concludes ...giving a detailed list of the directions in which the ...y is orientated in burial and in cremation by ...ous Indian peoples.

Rationale of Radiation Therapy.—The action ...adiations (both radium and X-ray) depends upon ... direct action upon the tissues, varying with the ...nsity of the radiations, (2) an indirect effect ...ced by the action upon the tissues and circulating ...ds. The subject is discussed in the *British ...rnal of Radiology* (B.I.R. section), vol. xxix., ... 289, August, p. 296. There is much evidence ...ch goes to prove that direct radiation of tumours ...duces in some cases an inhibiting effect upon cell ...elopment, and in others the cessation of activity ... the death of the cells. If a sufficient dose of radiations be given to certain tumours a lethal effect upon the tumour cells is induced. But in the majority of cases of tumour growth treated clinically, the administration of a lethal dose to the whole of a large tumour is a practical impossibility, because of the disastrous effects upon the organism as a whole, due to the secondary or reactionary action mentioned above. Other methods of application have therefore to be employed, *e.g.* subjecting the patient to sub-lethal doses extending over a considerable period, with intermittent administrations. "It is clear to most radiologists that the cure of cancer by radiations is at present beyond our reach, and that to claim cure would be to retard indefinitely the progress of radio-therapy in the treatment of cancer. To establish the proof of a definite degree of control upon tumour growth would be a great step forward in the attack upon this intractable disease."

The Life-History of the Indian Glow-worm.—Bulletin 69 of the Department of Agriculture, Ceylon, by Dr. J. C. Hutson and Mr. G. Douglas Austin, is devoted to an account of the habits and life-history of the Indian glow-worm (*Lamprophorus tenebrosus*). This insect is luminous in all its stages from the egg to the adult. The female is of large size (60-65 mm.), and is a pale yellow larviform creature, while the male is a winged insect, 20-30 mm. long. The female lays from 30 to about 100 eggs and broods over them during the incubation period; if removed from her eggs she soon finds her way back and curls up over them. If the eggs be scattered, she usually collects them one by one into a heap again. The incubation period is about seven weeks, and the male larvæ are stated to pass through only three or four instars, while the females have five or six. The larval period for both males and females is eight or nine months, and the whole developmental period occupies less than one year during normal conditions. The species is nocturnal in its habits, both larvæ and adults remaining in concealment during the day. The larvæ appear to feed normally on the African snail (*Achatina fulica*) and probably on other local snails. The African snail is a pest of young plants in vegetable and flower gardens, in some districts of Ceylon, and the larvæ of the glow-worm are probably of some value in reducing the numbers of this mollusc. Observations made in captivity indicate that a male glow-worm larva will destroy 20-40 snails during its life, while the female larva will account for 40-60 snails. The adult male and female glow-worms, however, were not observed to prey upon the snails. The snail has spread to new areas within recent years, and it is possible that the glow-worm is still absent from such districts. Experiments might be made to introduce it into such areas.

Eggs from Infected and Immunised Hens.—H. G. May finds that in hens fed or inoculated with living cultures of three bacteria pathogenic to them (fowl cholera, fowl typhoid, and white diarrhœa), although the ovaries are infected, the organisms do not pass into the eggs. (Bull. 197, Agricultural Experiment Station of the Rhode Island State College, U.S.A.) Agglutinins and germicidal substances were formed to some, but a variable, extent in hens immunised with these organisms, and a small amount of agglutinin passed over into the egg albumin. The albumin of eggs of normal hens in a dilution of 1 in 5 proved slightly germicidal to the organisms, and with one exception there was no increase in germicidal power of the egg albumin after immunisation of the hens.

NATURE OF *BLASTOCYSTIS HOMINIS*.—This is one of the commonest parasites met with in the human intestine, and its true nature has remained uncertain since its discovery some fifty years ago. Though quite harmless, it is of importance as being responsible for mistakes in diagnosis, having been frequently confused with the cysts of the amœba of dysentery. The earlier workers regarded it as a cystic form of various protozoa or as a degenerated leucocyte. Alexieff first put forward the view that Blastocystis is a vegetable organism allied to the Blastomyces group, and now Major R. Knowles and Assist. Surg. B. M. Das Gupta support this (*Ind. Journ. Med. Research*, vol. xii., No. 1, p. 31). They regard Blastocystis as a genus of the higher fungi, closely allied to the Schizosaccharomycetes, and probably containing several different species. The general life-cycle appears to consist of (*a*) multiplication by binary and multiple fission by plasmotomy; (*b*) multiplication by exogenous budding; and (*c*) multiplication by endogenous spore formation inside an ascus into which the paraglycogen mass is converted.

BRANCHING IN BUDDED CACAO.—Cacao grown from seed produces two types of branch with different leaf arrangements, the main axis terminating in five branches, and the lateral horizontal branches, which are of the "fan" type. Cacao plants grown vegetatively from buds are always of the "fan" type. Messrs. S. C. Harland and R. G. Parga discuss this problem in the September number of *Tropical Agriculture*. Their experiments show that budded cacao is always of the fan type because the buds are taken from the horizontal fan branches. If buds are taken from the main axis, the seedling type of tree can be produced, with normal dimorphic branching.

BOTANY OF THE ABOR EXPEDITION.—In the Records of the Botanical Survey of India, vol. 10, No. 1, Mr. I. H. Burkill describes his extensive collections and observations made during the Abor punitive expedition in 1911. The flora is of a highly mixed type, since this region lies on the boundary of the Asiatic cupuliferous zone, and yet contains elements from the tropical Gangetic floras. The Himalayan and Chinese floras also mingle in this vicinity, and these various elements of the vegetation are traced by Mr. Burkill to their origins. On account of its high rainfall, the country is chiefly covered by rain-forest, but a curious feature is the absence of pines on the hills, this being attributed to the high humidity and consequent excessive competition of dicotyledons. The typical rain-forests consist of a main level of animal-dispersed and often large-leaved trees and climbers, above which arise taller, wind-dispersed and small-leaved trees. At levels above 2000 feet the forest changes; Quercus and Castanopsis become dominant and tree ferns scarce. The most striking feature, ecologically, of Abor land appears to be that the type of climax forest is by no means uniform, but it is largely determined by the soil conditions. Thus on the Pleistocene gravels, *Terminalia myriocarpa* forms pure forests, these being nearly devoid of any climbing plants. Similarly, the Dipterocarp *Vatica Shingkeng* makes pure forests on north slopes over Siwalik and Gondwana rocks, an absence of mosses and prevalence of lichens being also a noteworthy feature of these areas.

COLD WINTERS IN SOUTH-CENTRAL EUROPE.—The *Monthly Weather Review* for April has an article by Dr. J. Maurer on "Severe winters in Southern Germany and Switzerland since the year 1400, determined from severe lake freezes." The article is translated from *Meteorologische Zeitschrift* for March by Mr. W. W. Reed of the Weather Bureau, Washington. The da for northern Germany show that in the period fr 1788 to 1845 there was an unusually large number severe winters, while since that period there have be far fewer. In the 58 years from 1788 to 1845 th were 17 very severe winters, and in 72 years from 18 to 1917 there were only 6. In southern Germany a Switzerland the occurrence of severe winters is qu different. From 1788 to 1845 there were only 3. South-Central Europe from 1435 to 1587 there w 15 severe winters in 153 years; from 1588 to 1680 severe winters in 92 years; in 1681 to 1800, 10 seve winters in 120 years; and in 1801 to 1923 there were severe winters in 123 years. It is mentioned that t recent small number of severe winters permits t conclusion that an offsetting will follow, but it difficult to predict when that will commence. T inquiry is said to indicate a kind of "climatic oscil tion" the cause of which lies completely hidde Without doubt cold winters in Central Europe affect a marked degree the severity of the winter in Weste Europe, but the absence of regular periodicity in t German data affords no aid for forecasting.

POLYPEPTIDES IN OATS.—Jodidi (Journ. Frank Instit. 198, 1924, pp. 201-211) has estimated t amount of peptide nitrogen in ungerminated oa (four varieties) as 0·03 to 0·1 per cent. of the d weight. Similar figures are given for the amino-ac and acid amide nitrogen.

THE CHEMISTRY OF COTTON.—The Journal of t Textile Institute (vol. 15, No. 8) contains two pape dealing with the chemistry of cotton. Messrs. P. Clifford and M. E. Probert (p. T401) give the resu of an examination of the constituents of the wax fro American cotton. A large proportion of this consis of free wax alcohols, but few wax esters being prese A new sterol, $C_{34}H_{58}O$, was detected and examine In the same number (p. T414), Mr. H. J. P. Ve records the yields of β-glucosane obtained by l pressure distillation of cotton after various trea ments. Raw cotton gives no β-glucosane on d tillation—the water and acid soluble mineral su stances must be previously removed. The highe yield obtained was 37 per cent., and rather low values were obtained for American cotton than f Egyptian, the two varieties differing also in oth respects.

QUARTZ GLASS MANUFACTURE.—The issue of t *Physikalische Zeitschrift* for August 1 contains description by Dr. von Schwarz of the Herberg method, which has been in use for the last 11 years the firm of Goertz, for producing quartz glass f therapeutic and other scientific purposes. The fine divided quartz is melted in an electric furnace which a vacuum is maintained by continuous pumpi until the melting process is complete. The vacuum then replaced by a gas such as carbonic acid gas unc a pressure of 8 to 12 atmospheres, and after a co siderable time the fused quartz is allowed to co The result is a block of quartz containing only minu air bubbles in which the air pressure is as nearly possible that of the atmosphere and therefore produc no elastic stresses in the material. According observations made by Dr. G. Joos and described the same issue, quartz glass made in this way is transparent in the ultra-violet as rock crystal.

KERR'S ELECTRO-OPTICAL EFFECT IN GASES.—T effect was observed in gases by Hansen; but he ma use of ordinary white light, so that his results are n sufficient for testing the different theories of t phenomenon. The simplest conditions prevail in gas, since the molecules are separated from o

ther, and each molecule may be considered as eig acted on by the electric field, and as acting on transmitted beam of light, independently of the t r molecules. Herr G. Szivessy describes the hod employed by him with sulphur dioxide, monia, and carbon dioxide in the *Zeitschrift für ysik* of Aug. 12. A beam of light from a powerful lamp was sent through a monochromator and a rising nicol into a long vessel filled with the gas, between the plates of a condenser inside the el which produced a field inclined at 45° to the ie of polarisation. On emergence the light passed ough a Brace half-shade compensator into the erving telescope. Pressures up to about 1500 cm. nercury were employed, using wave-lengths from 8 to 656 $m\mu$; it was not found possible to study the ct of temperature variation, and the temperature kept nearly constant at about 17·5° C. The ults obtained show that the electrical double action is proportional to the field intensity, eeing with Kerr's law; with constant wave-length r's constant is proportional to the pressure, and h constant pressure is inversely proportional to wave-length.

ONISATION BY POSITIVE IONS.—Dr. J. Franck, in *Zeitschrift für Physik*, Aug. 4, shows that in order ionise another atom by collision the positive ion rst have at least the kinetic energy $\frac{1}{2}mv^2 = 2(I + P)$, were I is the ionisation energy and P is the potential ergy which the first ion and the new ion produced the collision have with regard to one another. I is known for many kinds of atom, and P is approxiately the potential energy which two particles with positive charges possess when their distance apart is the sum of the radii of the atom and of the ion. It may, however, be necessary to take mutual polarisation into account. The number of such collisions is small. Ionisation can take place for smaller kinetic ergy if the ion, instead of ionising by direct collision, ges up its energy to another atom, which then collides with a third, thus ionising it. Collisions tween ions and atoms may excite the atom, which ay then be ionised by collision with another atom. is estimated that the lowest kinetic energy of the ion which can in the end produce ionisation is about I, but the effect will then be very small. The case ionisation due to the collision of ions having large nisation energy with easily ionised atoms is discussed; very small kinetic energy may then produce nisation, as when Hg ions ionise the alkali metals. he phenomenon of the pseudo-high vacuum in pure re gases, and the effect of traces of impurity, epends on the difference between the ionising energy the rare gas and of the impurity. In the pure gas, sufficient number of electrons is not produced near e cathode to allow of discharge; but the positive ns of the rare gas act on the molecules of the purity, producing the necessary electrons.

GLOBULAR LIGHTNING AND THE CAUSE OF THUNDER.—M. E. Mathias, in the *Comptes rendus*, Paris Acad. ci. July 21 and Aug. 18, suggests that in a lightning scharge heavy complicated molecules are formed ndothermically, and that sometimes, when an exedingly violent discharge takes place close to the round where the air is a bad conductor, a short flash ith a relatively large section will be produced, giving cylinder filled with hot, heavy gas. This falls and ontracts in length until it becomes more or less lobular, and it is suggested that even in the case of ases there is some kind of surface tension at the oundary between two different fluids which can roduce this result. The phenomenon was observed h detail by M. Koechlin on May 21 last, the cylinder being dazzling white at first, and the colour changing during the fall to yellow and finally to fiery red. This indicates a cooling of the mass, which finally explodes with a violent crash, the heavy gases suddenly decomposing with the formation of O_2, N_2 and a certain amount of ozone, which gives a characteristic odour. Complex molecules, such as O_{12}, N_{12}, O_6, N_6, O_4, N_4, may be formed by the discharge; and it may be that, even in an ordinary lightning flash, the main detonation of the thunder takes place some little time after the flash, when the heavy gases formed have cooled down sufficiently to explode. At the instant when the discharge takes place, a reduction of pressure is produced along the flash, owing to the formation of complex molecules, and this may cause a crack of sound; but the main detonation comes later, when these molecules suddenly decompose.

MANGANESE STEELS.—The more extensive use of steels containing from 1-1·5 per cent. of manganese has been frequently suggested on account of the superiority of their properties over those of carbon steel, especially when heat-treated. R.D. Report No. 61 from the Research Department, Woolwich, gives an account of an investigation on the properties of medium carbon steel with high manganese content, by J. A. Jones. It appears from his results that after oil-hardening at 850° C. and tempering at 650° C., all the mechanical properties of a 0·4 per cent. carbon steel are improved by the presence of about 2 per cent. of manganese. The improvement is still maintained at 3 per cent., but the additional manganese shows no advantage and may introduce difficulties in forging. Steels with high manganese content are extemely liable to show temperature brittleness when slow rates of cooling after tempering are employed, but this may be avoided by suitable heat treatment. If good impact figures are to be secured, the cooling from the tempering temperature must never be slower than in air. The author finds that the critical points Ac_1 and A_1 are lowered by the increasing amounts of manganese. In this he confirms the work of previous investigators. Ac_3 and Ar_3 are also lowered, and with sufficient manganese merge into Ac_1 and Ar_1 respectively. The presence of manganese tends to prevent the separation of ferrite and pearlite on cooling. For purposes for which it is desired to replace carbon steel forgings by steels of greater strength, the author suggests carbon from 0·35 to 0·40 per cent., manganese from 1·8 to 2·2 per cent., oil-hardened from 800° to 850°, tempering from 610° to 650° C., and cooling in air, oil, or water.

A PORTABLE MICROSCOPE.—In their "Baby London Microscope" Messrs. R. and J. Beck, Ltd. (68 Cornhill, E.C.3), have constructed the most portable microscope yet produced, for it is contained in a case measuring only $5\frac{1}{4} \times 2\frac{1}{2} \times 2$ in. The tripod stand folds up, but when extended the microscope is quite stable. It has a sliding coarse adjustment and an extending draw-tube giving a tube length of 160 mm. The fine adjustment is sufficiently delicate for use with an oil immersion objective and the objective screw is the standard R.M.S. one. The tube similarly takes the standard size eyepieces. The microscope may thus be used with all standard objectives and eyepieces, though it is primarily intended for nature study in the field. For this purpose, a special $\frac{2}{3}$ in. objective is supplied, so that the microscope will pack into its case when it is in position. The mirror is concave and provided with all adjustments, but for high-power work a condenser and flat mirror may be added. Examination of the instrument has justified the claims as to portability and performance put forward by the makers.

The Ascent of Sap and Transport of Food Materials in Trees.

IN opening the discussion on this subject in Section K (Botany) of the British Association, on August 7, at Toronto, Prof. H. H. Dixon affirmed that the cohesion theory of the ascent of sap has recently received important support from the observation of continuous water-columns in the tracheæ of wilted plants by Holle and Bode, from the new determinations of the tensile strength of water by Renner and Ursprung, and from the observations of the collapse of the transmitting wood, and even of its constituent tracheæ under the tension developed during transpiration, and of their recovery on the rupture of the tensile water-columns. The water in the tracheæ, which passes into a state of tension, has been shown to contain carbohydrates and other foodstuffs. When the movement is upward in the tracheæ, due to transpiration and the supply from the roots, these foodstuffs are carried upwards in the stream. If for any reason a downward movement is originated these foodstuffs will evidently be carried downwards. Such a downward movement may be established by cutting a leaf of a transpiring plant under water. The downward movement may be visibly traced by adding eosin to the supply to the leaf. Thus in a short time the tracheæ of the tuber of a transpiring potato plant has been shown to become infected with eosin from one of its upper leaves. In this case transpiration from some leaf-areas has drawn the eosin solution from the cut leaf downwards into the tuber. In a similar manner, we may suppose that the foodstuffs manufactured by the leaves are transported. The reversal of the transpiration stream, artificially produced in the above experiment, probably often occurs naturally. This is suggested by the backward transport of hormones in the wood, recently demonstrated by Ricca in Mimosa, and probably occurring in other cases of transmitted stimuli.

The physical properties of the bast, and its available cross-section, render it impossible to suppose that the transference of foodstuffs takes place in the bast. An increase in the permeability of regions of the mesophyll around certain bundle-endings may render the contents of these cell-masses available as sources from which the tensile sap in the plant draws. It was assumed that the fluid thus introduced into the tracheæ is dragged backwards in the conducting tracts by the transpiration of other parts. Experiments were further quoted showing the change of permeability with temperature, and also the variations in the temperatures of leaves under natural conditions. It was contended that such temperature-changes may be, in part at least, responsible for permeability-changes which originate backward movements in the water conduits, and hence facilitate the distribution of foodstuffs throughout the plant.

In conclusion, Prof. Dixon held that although it could not be affirmed that evidence amounting to a demonstration of the validity of the cohesion theory was available, nevertheless the theory as at present formulated seemed in harmony with the known facts.

In following with an account of recent experiments bearing on the transport of foods in woody plants, Dr. O. F. Curtis stated that when ringing experiments were performed during the growing season, materials necessary to growth would not move upwards through the xylem past the ring. Analyses and cryoscopic determinations indicated that the movement of sugars and other solutes was interfered with by the ring. When, just previous to spring-growth, rings were made at different distances from the tip of a branch, the growth above the rings was roughly proportional to the amount of food stored above the rin Quantitative tests were held to indicate that t upward transfer of carbohydrates had been interfer with by the rings. It was further held that wh the xylem of a given region of the stem was isolat by rings through the phlœm from other tissues whi would normally receive carbohydrates from the wo or supply the latter with carbohydrates, no mov ment of such carbohydrates out of or into this regi of the xylem occurred. It was further stated th the normal upward movement of nitrogen and as constituents was interfered with, though not co pletely stopped, when the phlœm was cut. Th occurred whether the ring was made in the ear spring before new xylem and leaves were formed, in midsummer after growth was practically comple The evidence obtained from ringing experiments w held to indicate that the influence of the ring on t upward movement of nitrogen was independent its effects on the organic content of this part abo the ring or on transpiration.

In more or less direct opposition to the vie expressed by Prof. Dixon, it was finally affirmed th experiments with spiral ringing of stems provi further supporting evidence for the opinion th foods and nutrients travel both upwards and dow wards in higher plants chiefly in the phlœm.

Dr. D. F. MacDougal followed with a detail statement of experiments conducted by the aid of dendrograph. The purpose of his communication w to lay before the section his observations on variatio in volume of trees, and in the movements of liqui within them. He stated that dendrographic measur ments of several species of trees show that the trun undergo variations in volume which may be corr lated directly with the transpiratory activity green surfaces, which in turn varies with the widt of the stomatal slits. The period in which stomat slits are widest is one of contraction of the trunk closure of stomata is accompanied or followed b expansion of the trunks. Contraction of the trunk or stems of mesophytes and sclerophylls takes pla in the daytime; contraction of flattened or cylindric stems of cacti takes place at night and expansion i the daytime, in reverse of the occurrences in the mo general type.

The time or hour at which these two phases variation prevail changes with the season. At th time of maximum growth, contraction in coniferou trees may begin within a half-hour after sunris Such reversible variations are modifiable by change in relative humidity, by defoliation, girdling, toppin or any agency which alters transpiration or rate c conduction, and are explainable on the basis c Prof. Dixon's conception of the mechanism of th ascent of sap. The upward path of moving solution of a basic dye, such as fuchsin, is found to be in th wood formed within the previous two years. Whe two layers are formed in a season conduction i chiefly in the one formed earlier. Whether the othe layers are more available or suitable for the down ward conduction of organic material is yet to b tested.

The amount of reversible variation in the diamete of a young pine may be 1 part in 170; in the uppe part of a tree approaching maturity 1 part in 900 in the basal region 1 part in 1700; in a large roo 1 part in 364. As this variation takes place chiefl in the outer wood, it is found that in such recentl formed layers the coefficient of expansion and con traction may be five to ten times greater than tha of the trunk taken as a whole, as given above.

the discussion which followed Prof. Priestley ...ged that he had been a supporter of the cohesion ...ory of the ascent of sap, but that he was now so ...pressed with Copeland's criticism of the theory ...h he considered the latter incapable of meeting ...y the criticism which it had raised. He desired ...point out that Prof. Dixon had not replied to ...eland's challenge, demanding as it did an explana... as to how energy is employed in raising water ...the stem. He further declared that no plant-...cture had yet been shown to be capable of ...sting the tensions which the cohesion theory ...posed to be developed in the tree.

...rof. Overton expressed himself in general agree...nt with the cohesion theory, while Prof. V. H. ...ckman considered that much work had yet ...be done before a valid theory of the transport ...organic substances could be constructed. There ...e difficulties in admitting that the wood furnished ...ownward path for organic substances, while at the ...ne time it was engaged in transmitting the upward ...spiration stream. In his opinion it seemed ...ily improbable that the bast is without a function. ...Whatever the function of the bast, he felt that it was ...ociated with the downward transmission of food-...iffs.

...n replying to the views which had been expressed, ...f. Dixon stated that in his opinion Dr. Curtis had ...t allowed sufficiently for the plugging arising in ...ged stems. It was pointed out that the results of ...Curtis's experiments on branches with extirpated ...od and on those the bast of which had been removed ...ry, from the arrangements described, be explained ...the known difference of resistance of wood to the ...nsmission of water in a radial and in a longitudinal ...ection. In the opinion of Prof. Dixon the experiments described by Dr. Curtis did not necessarily indicate the transmission of food materials by the bast. Replying to Prof. Priestley it was pointed out that the energy for raising water in plants is applied by the transpiring cells in contact with the upper terminations of the conducting tracts. This energy is supplied by the inflow of heat at the evaporating cells or by the stored energy in the cells themselves. The tensions developed in the water are withstood by the strength of the thickened tracheal walls and by the osmotic pressures developed in the adjoining cells.

In conclusion, Prof. Dixon expressed himself in agreement with Prof. Blackman regarding the need for fuller inquiry on the subject under discussion before any theory of the ascent of sap and the transport of organic materials in plants could be generally accepted. He held that it is quite in accordance with the known structure and properties of the tracheal tissues, that upward and downward currents may be simultaneously passing in adjacent tracts. The small resistance offered by the wood to the longitudinal movement of water, compared with that which it opposes to transverse movement, secures the isolation of these two streams. Lest the unemployment of the bast should be used as a reproach against the cohesion theory of the transport of foodstuffs in the wood, he suggested that the companion-cells are glandular in function, and secrete enzymes which digest the colloids in the tracheæ. The sieve-tubes, he held, may be regarded as temporary reservoirs of these enzymes, while to the cells of the wood-parenchyma and medullary rays may be allocated the functions of introducing these enzymes into the tracheæ and of abstracting food materials from them.

J. McL. T.

Aeronautical Research.

THE issue of the report for the year 1923–1924 of ... the Government Aeronautical Research Com...ittee is of more than ordinary interest, since it ...cords that the desire expressed by the Committee, ...at greater recognition should be given to the claims ...pure research, has been recognised, in one import...t respect, by the reorganisation of the old director...te of research at the Air Ministry into two new ...partments, namely, a Directorate of Technical ...velopment and a Directorate of Scientific ...search.

It is gratifying that the Committee is able to record ...eady progress in the different subjects embraced ...by the science of aeronautics. Research having a ...rect application to aeronautics is financed by the ...Ministry; the remainder, having a more general ...plication, is financed by the Department of ...ientific and Industrial Research.

Investigations on elasticity and fatigue of various ...tals have been arranged in the Universities of ...ford, Birmingham, and Liverpool; investigations ...single-cylinder internal combustion engines have ...en started in the Universities of Cambridge, ...rham, and Manchester, and in the City and Guilds ...ngineering) College. In addition, there are the ...olly subsidised researches carried out at the Royal ...rcraft Establishment, the National Physical Labo...tory, and the Air Ministry Laboratory in the ...perial College of Science and Technology, London.

The general field of work is so extensive that a ...al concentration on specific problems is necessary. ...the year under review, one of the most important ...the problems which has received attention is the ...ntrol and stability of airplanes; the Committee ...stifies concentration on the attempt to secure low-...eed control by the continued occurrence of accidents in which "spinning" is a primary or secondary feature. In this direction, slow but steady progress is recorded. It had been suspected for some time that one of the main reasons for loss of control in a stalled airplane lay in the fact that ordinary ailerons, besides applying a moment to roll the machine, also cause it to turn, which turn eventually introduces moments which defeat the primary action of the ailerons and render them ineffective.

A larger rudder is thought to be a part solution: a rudder of ordinary size may be capable of providing all the turning moment required in normal flight, but may prove inadequate in stalled flight, in that it must become less effective through being shielded by the body when the incidence is large, and because larger moments are required from it in order to balance those set up by the wings and by the ailerons.

The difficult problems of the cause of detonation in engines, and of the steps necessary to eliminate this feature in high-compression units, has been under consideration, and attention has been given to the bearing of American work in this field of investigation. Experimental work on engines has been undertaken in the Government establishments and in the Ricardo Research Laboratory.

The Committee records the Air Council's agreement with the view that a higher standard of technical knowledge in all ranks of the R.A.F., and particularly among squadron officers, is necessary, and states that steps have been taken to organise instructional courses at Cambridge and the Imperial College with this end in view.

The report is of modest dimensions; its form is that of a 50-page paper-covered pamphlet, and its issue price, 2*s.* 6*d.*, through H.M. Stationery Office, seems somewhat high.

Radio Communication and Research in Great Britain.

BY what means is it possible to confine the reception of radio signals to certain well-defined localities? The limiting of the radiation from a transmitting station to moderately definite directions is a *fait accompli* so far as radio signals of short wavelength are concerned, but a full solution of the larger problem is still awaited. If the regulations governing the use of radio apparatus in Great Britain for experimental and research purposes, as set out in the recently issued revised Post Office licenses, were to be taken seriously, it might be imagined that the solution of the problem is quite well known. The futility of attempting to regulate to certain frontier boundaries the transmission and reception of radio signals, as is apparently required by the rule which states that "Messages shall be transmitted only to stations in Great Britain or Northern Ireland," was discussed at some length in the autumn presidential address to the Radio Society of Great Britain which was delivered by Dr. W. H. Eccles at the Institution of Electrical Engineers on September 24. Such attempted restrictions on research work cannot be to the credit of the country or help friendly international relations in any possible way.

The experimental tests which, during the past three years, have been carried out between radio amateur experimenters in almost every civilised country of the globe have undoubtedly fostered a feeling of good fellowship between those workers—a feeling which cannot but be to the good of all the countries concerned. But what, indeed, are foreign amateurs to think of us if in the future we consistently refuse to reply to their signals and ignore all calls addressed to us through a too rigid adherence to the terms of our licenses?

The official ban on communications with stations outside the limits of "Great Britain and Northern Ireland" is not even lifted in the cases of the British Colonies, but fortunately (since it may encourage British Government officials to a wider outlook in due time) such views are not held by other countries, as is shown by the following message recently se to the Radio Society from the Canadian Ra Relay League, a large and influential organisation radio enthusiasts :—

"Please convey our greetings to the Radio Socie of Great Britain with congratulations on their achie ments. We also congratulate the Transmitter a Relay Section [of the Society] on their wonder success in the transatlantic tests, and take this opp tunity of expressing our desire for a stronger affiliati between Great Britain and the Colonies for the gene benefit of amateur radio."

In most countries where experimental radio licens are granted, the facilities given with the license a much greater than they are in Great Britain, but view of the pioneer development work that has be carried out by the radio amateur in recent years, seems scarcely justifiable to attempt to increase t restrictions upon him.

It should be remembered in this connexion that was the radio amateurs who discovered the valuat properties of short C.W. waves for signalling over lo distances. Up to three years ago the commerc companies and most radio engineers thought that t shorter wave-lengths were of no use for long distanc but radio amateurs, particularly in England, Fran Canada, and the United States, gradually extend the ranges across which communication could carried on with these waves until, as a result of t transatlantic tests conducted by the Radio Society Great Britain and the American Radio Relay Leagu the incredulous ones looked into the matter. Sin those tests the engineers of the great radio compani of the world have been rapidly investigating the short wave transmissions and carrying on with high powers and on a larger scale the initial experimen It seems, therefore, undesirable that there should another bar to research in Great Britain in a field which the amateurs in particular have already do good work.

P. R. C.

The Biology of the Suez Canal.

THE Cambridge expedition for the investigation of the intermingling of the Mediterranean and Red Sea organisms in the Suez Canal left England last week in the Orient liner *Orcades*. The fauna of the Canal, which was opened in 1869, was first studied by Keller in 1882, a later reinvestigation of the fishes being made by Tillier in 1903. The organisms of the Red Sea and the Mediterranean are very different from one another, even though these two seas were connected by a narrow strait, approximately along the line of the Canal, in glacial times. The barrier to intermingling at that period would seem to have been fresh water, a considerable Nile mouth opening into the centre of the strait. In the time of the Pharaohs a navigable canal was dug, connecting a branch of the delta with the Gulf of Suez, which then extended about 30 miles farther north. By the time of Cleopatra this canal became impassable, owing to Nile silt, but it was afterwards reopened, being finally closed for strategic reasons by the Caliph Almansur towards the end of the eighth century. French investigations, carried out at Suez when Napoleon was in occupation of Egypt, showed certain Mediterranean jelly-fish, sea anemones, and other forms which did and do not extend to the south out of the gulf of the same name. These, if they passed by the Canal, must have been able to withstand the fresh water in its centre. The conditions then were the opposite to those of the present day, for t Bitter Lakes have now a salinity of about 77 gra per litre, or about twice the salinity of either of t terminal seas. These Lakes will be intensive studied, while the fauna of the brine pools in t deserts bordering on the Canal will also be examined

The Suez Canal Company is giving facilities respect to boats and by the use of its Canal Statio and it is hoped to carry the investigation to at lea two areas on either side of the Lakes. Each will intensively collected by trawl nets, dredges, a tow-nets of different sorts, while samples of t bottom and its contained fauna will be obtained means of the Petersen grab. Similar methods w be adopted at each place, so that comparisons will possible, not only as to the different species found each, but also to their relative numbers. The anima will probably be those which live in more or le moving sand, and special gear has been devised secure these. Then there are such swimming forn as fishes and a few crustaceans. Hard bottom for t attachment of sedentary organisms would only see to be present in a limited area in the Lakes, but the are piles and other artificial erections, and sunke vessels, in places; however, the larvæ of all a practically free living. The problems before t expedition are to ascertain what forms have passe through the Canal zone from the Mediterranean

the Red Sea and vice versa, when they passed through, whether in the prehistoric period, in the times of the earlier or of the present canal, how they passed through, whether by swimming, by drifting, by attachment to ships, or by other means. All these facts lead up to the question why some forms of life can get through the Canal and others cannot, and it is hoped that the expedition will throw light on marine migrations in general, the area being one which can be periodically investigated at small cost.

The expedition is in charge of Mr. H. M. Fox, Balfour Research Student of the University, who is responsible for the necessary physical, chemical, and physiological work. He is accompanied by Mr. Robert Gurney, who undertakes the plankton, and by two research students of the University. It has been arranged by a Cambridge committee, of which Sir Arthur Shipley is chairman, and is largely financed by the government grant administered by the Royal Society; collecting gear has been provided by the University and the Natural History Museum. It is a return to the former tradition that the Balfour student should undertake for part of his period of research an expedition to investigate some problem in the field.

J. STANLEY GARDINER.

University and Educational Intelligence.

DURHAM.—Applications are invited for a lectureship in geology at Armstrong College. The latest date for the receipt of applications (10 copies of each) is October 25. They should be addressed to the Registrar, Armstrong College, Newcastle-upon-Tyne.

LEEDS.—A programme has now been issued of the Celebration Week to be held on December 15-20 to commemorate the jubilee of the Yorkshire College of Science and the coming of age of the University. The ceremonies will include a number of receptions by local bodies, public lectures on the educational and architectural history of the University by Prof. A. J. Grant and Dr. A. Hamilton Thompson respectively, and on the aims of university education, by Sir Michael Sadler. A portrait is to be presented to Sir Michael Sadler in recognition of his manifold services to the University. Most of the ceremonies will be open to the public, and on the last day the whole University will be thrown open for inspection.

LONDON.—The University College Committee will shortly appoint a Quain student in biology. The value of the studentship is 150*l.* per annum, and it is tenable for three years. Applicants must have been already students of University College in the subject of botany. Full particulars can be obtained from the Secretary, University College.

Free public lectures will be given (in English) at 5.30 o'clock at King's College, on October 16 and 17, by Prof. H. Wieland, of the University of Freiburg, on, respectively, "Organic Radicals" and "The Theory of Oxidation Processes." No tickets will be required.

APPLICATIONS are invited by the Glamorgan Agricultural Committee for the position of Instructor in Agriculture under the Director of Agriculture. Candidates must be practical agriculturists, able to lecture and demonstrate in agriculture and allied subjects and to conduct field and live-stock experiments. Application forms (which must be returned not later than the morning of October 13) may be had from the Director of Agriculture, 5 Pembroke Terrace, Cardiff.

AT the meeting of the Scottish Universities Entrance Board held on September 27, Sir Richard Lodge, who was in the chair, alluded to the loss which the Board had sustained in the death of one of its members—Prof. Darroch. The following resolution was unanimously adopted, and it was agreed that a copy of it should be sent, with an expression of the Board's sympathy, to the late professor's daughter: "Prof. Darroch was an original member of the Scottish Universities Entrance Board as a representative of the University of Edinburgh. His unique knowledge of the educational system of Scotland, his shrewdness of judgment, and the careful thought and labour which he gave to the business of the Board, made him one of its ablest and most useful members. His colleagues desire to place upon record their appreciation of his services and their intense regret at the untimely end of a life which had been devoted to the cause of Scottish education."

AT the meeting of Convocation to be held on October 14, a chairman is to be elected to succeed the late Dr. R. M. Walmsley. There are two nominations for this important office, namely, Prof. S. L. Loney, whose mathematical books and activities in connexion with the work of the University are well known, and Sir Robert Blair, who was the Education Officer of the London County Council for twenty years. Sir Robert Blair has long been associated with the progress of science teaching in the schools. So far back as the British Association Meeting in 1910, he was pressing the claims of the technical and scientific expert for higher posts in industry and commerce: he has been a pioneer in technical education and has persistently advocated the need for training at universities and higher technical institutions. His knowledge and administrative experience should be of decided value to the University if he is elected chairman of Convocation.

THE "gifted pupil" in the high schools of Iowa forms the subject of a study, published in Bulletin, 1923, No. 46, of the Bureau of Education, Washington, by Charles Deich, professor of education, Simpson College, and Elmer E. Jones, director, School of Education, Northwestern University. That it is the duty of educational administrators to provide for the early identification of sub-normal children and the adaptation of their schooling to their special needs has long been recognised, but it is now coming to be realised that it is quite as important that supernormal children should not be retarded in their development through being made to conform to mediocrity. The Association of American Universities discussed in 1922 "The sifting out of the exceptional student and his relationship to the university curriculum"; the writers of the more recent Iowa report contend that too often irreparable mischief is done at an earlier stage: "If he is hampered by association with mediocrity, and if his course is not broadened and deepened to meet intellectual abilities and desires, he is doomed to a type of retardation that is wellnigh impossible to counteract in later educational work. No matter what his college life may be, or how excellent his graduate work, he has sustained a loss in his secondary training that can never be replaced." Accordingly, it is recommended that there should be in each year a survey of the schools undertaken in co-operation with university departments of education and psychology. By using the data thus obtained, teachers in the high schools would be able to identify the exceptionally gifted students with certainty by the beginning of their third high school year, and arrangements could be made for providing for them suitably enlarged and intensified courses.

Early Science at the Royal Society.

October 4, 1667. Mr. Charles Howard suggested, that it might be considered, whether maiz might not yield a kind of sugar, the stalks of it containing a very sweet juice; and he desiring, that he might be furnished with an account of the way of ordering the sugar-canes for the making of sugar, Mr. Oldenburg offered an account relating to Barbadoes.

October 5, 1661. Sir Robert Moray produced unnealed glass hollow balls with a small hole in them; which being held in the hand till they were heated (the hole thereof being stopped with the palm of the hand) would fly to pieces.—Dr. Goddard to try the velocity of sinking bladders in water, and the lord viscount Brouncker in air.—Dr. Ent to give in writing some considerations, why it is hotter in summer than in winter.

October 7, 1670. There was read a Latin letter from Signor Montanari, containing some new observations by him of the non-appearance of some stars of the second magnitude in the sky, though formerly observed by Bayer and others; and intimating that he had sent a manuscript, containing various experiments on the breaking of the glass drops, a task imposed on him by the grand duke of Tuscany.

October 8, 1662. Mr. Boyle was desired to shew, at the next meeting, the second part of his experiment about coagulation, viz., the reducing the coagulated liquors to their former fluidity.

October 9, 1661. A living chameleon was presented to the society from Mr. Clayton by Dr. Henshaw.—Dr. Croune, Dr. Pope and Mr. Rooke were appointed a committee to view the propositions for inquiries in foreign parts.—The lord viscount Brouncker read a letter of Dr. Christopher Wren to Sir Paul Neile, concerning his hypothesis of Saturn.

1673. The president gave the council notice, that there had been lately with him a committee of the professors of Gresham College, and another of the Mercers company, inviting the Royal Society to return to that college, and to keep their assemblies there, as formerly they did before the fire. To whom he had returned his thanks for this kind offer, and for their respect to the Royal Society. The council thought good to have their hearty thanks returned to the said committee for their kindness and respect, yet without saying anything to them of acceptance or not acceptance; only, in case they should give occasion for saying more, that then it might be mentioned, that the business was under consideration. The persons appointed to give these thanks were the lord viscount Stafford, Sir Paul Neile, Sir John Lowther, Mr. Pepys, Mr. Colwall, Dr. Croune and Mr. Oldenburg, or any three of them.—Whilst this was doing, Sir Theodore de Vaux came in, being sent by the earl of Norfolk, earl marshal, to acquaint the council, that his lordship wondered, that they were not met in Arundel-house, as formerly, but yet hoped, that they would hereafter still continue their meetings there, as formerly; and that if they should remove to any other place, he could not but take it very unkindly.—Hereupon the president declared, that for this time he had caused the council to be summoned in this place (his own house?) for his particular convenience, his present occasions not having permitted him to go far off. And his lordship, at the desire of the council returned their hearty thanks to the earl marshal for his singular affection and respect to the Society.

October 11, 1669. Ordered that Dr. Merret be desired to send the collection made by Thomas Willisel in his first voyage, to the society at their next meeting at Arundel-house.

Societies and Academies.

LONDON.

The Institute of Metals (Autumn Meeting), September 10.—D. M. **Fairlie** and G. B. **Brook** The determination of sodium in aluminium.—D. **Ingall**: The relationship between tensile strength temperature, and cold-work in some pure metals a single solid solutions. The critical inflection temperature is the all-important property of any metal alloy for high temperature service, as it would appe to be the temperature above which viscous flow ma take place and below which there is only stability the material in the cold-worked state. Other thing being equal, the higher the critical inflection temperature, the more suitable is the material.—H. **Moore** On the effect of progressive cold-rolling on the Brine hardness of copper. It has been stated that in th cold-rolling of copper, iron, tin and other metals ar alloys the Brinell hardness rises rapidly during th initial stages of deformation and then diminishe Experiments carried out at the Research Departmen Woolwich, give no support to the suggestion tha severe cold-rolling of copper beyond a certain stag induces softening.—F. W. **Rowe**: (1) Some exper ments on the effect of casting temperature and hea treatment on the physical properties of a high-t bronze. The bronze of the highest tin conte (copper, 86·0 : tin, 15·95 : phosphorus, 0·05) used in en gineering practice is employed for special bearing where low tin phosphor bronzes and leaded phosph bronzes have been found unsatisfactory. This allo attains its greatest hardness (and probably be wearing properties) with the lowest casting temper ture; this is, however, very often not practicab on account of the danger of "draws" in uneve sectioned castings.—(2) Some experiments on th influence of casting temperature and mass on th physical properties of Admiralty gun-metal. Admi alty gun-metal (copper, 88 : tin, 10 : zinc, 2) gives th best results in all sizes of bars with the lowest castin temperature, *i.e.* 1100° C., and the best tests of a with the ½ in. square bar cast at that temperature.—Tomojiro **Tanabe**: Studies in the aluminium-zin system.—T. H. **Turner** and W. E. **Ballard**: Meta spraying and sprayed metal. The process of metallisa tion invented shortly before the War and know generally as Schoop's metal spray process was hel back in its development by the unsettled conditio of industry, but is now being operated commercially The gas-operated metal spraying pistol now used i Great Britain and a rumbling barrel type of metallisin apparatus which is used for repetition work on sma articles were illustrated. All articles to be spraye are sandblasted and, in certain cases, preheating c the article to be coated is recommended, as this als tends to improve the adhesion. By spraying lightl on to glass slips it has been possible to examine th individual particles of the sprayed metals. Photo micrographs of these show that the metal must b molten at the instant it strikes the surface to b coated. Solid articles have been built up by sprayin and proved machineable and resonant. Practically any metal available in wire form and fusible in th oxy-hydrogen flame may be sprayed on to practicall any surface, *e.g.* on to paper, fabric, wood, or metal The surface produced is always matte, but may b polished if desired. The matte surface is an idea foundation for paints. Completed structures can b coated uniformly with any desired metal for pro tection against atmospheric corrosion, chemical attack or furnace conditions. The process has found a particular field in ship work, and is recommended fo the zincing of rail ends and fishplates for connectin purposes on electric railways.

Paris.

Academy of Sciences, September 1.—M. Guillaume Bigourdan in the chair.—MM. **d'Arsonval, Bordas,** and **Juplain**: Study of the waters of the glaciers of the Mont Blanc massif. The chemical and microscopical analyses of the sediments show that the Tour, Argentière, and Bois glaciers form one group: the Bossons Glacier shows peculiarities differentiating it from the others, on account of its intense mechanical effects on the underlying strata.—Henri **Jumelle**: Rodypsis, palm trees of Madagascar.—Maurice **Fschoud**: Calculation of the velocities for the steady state, by polynomials, in tubes with regular polygonal sections.—E. **Jouguet**: The speed of deflagrations. Development of results given in earlier communications, the hypothesis of a monomolecular chemical reaction being abandoned.—**Jarry-Desloges**: Contribution to the study of the planets Mars and Jupiter. Details of the changes observed in the appearance of the southern polar cap of Mars.—Ch. Ellissot: A simple arrangement for observing the optical disturbances in the atmosphere: application to the estimation of the definition of the images given by instruments. These disturbances are of interest in two directions, as limiting the accuracy of observations and as a means of supplying information concerning the movements of the atmosphere. A simple form of Fresnel's biprism is fixed to the objective of a small telescope and this is focussed on the objective of an astronomical telescope. Two half images are obtained, which may be either separated by a dark band, or partially superimposed, depending on the relative positions of the crest of the biprism and the focus of L. If the incident rays are free from disturbance, the exact position of the focus is sharply shown by the disappearance of the dark band. Optical discontinuities in the atmosphere are shown as striæ.—L. **Dunoyer** and P. **Thoulon**: Some electro-optical applications of arc relays. The principle of these relays has been described in an earlier communication (*Comptes rendus*, 1924, 148). Applications to optical signalling, directed optical radiotelephony, registration and reproduction of speech, television, and optical reception of radioelectric signals are described.—L. **Hackspill** and R. **Grandfam**: The saturated vapour pressures of mixtures of sodium and potassium chlorides.—H. **Gault** and C. **Truffault**: The chlorination of chloroform. The effects of light, temperature, and of various catalysts in the course of chlorination of chloroform was studied. Chlorination was prevented by the addition of ferric chloride to the chloroform, and this was shown to be due to the coloured solution absorbing the light rays determining chlorination.—David **Rotman-Roman**: The bostonites and camptonites of the Yemen.—M. E. **Denaeyer**: New observations on the geology of Tibesti - Djado - Kaouar.—Georges **Dubois**: Classification of the Quaternary of the north of France and comparison with the Danish Quaternary.—Mlle. Aimée **Camus**: New genera of Madagascan Bambusæ.—F. **Picard**: Observations on the solubility of the tannins and their extraction from plants.—Jean **Bathelier**: The development of *Euterpes matangensis*.—G. **Ramon**: The appearance of antibodies.

Melbourne.

Royal Society of Victoria, July 17.—Prof. Laby in the chair.—E. T. **Quayle**: Sun-spots and Australian rainfall. When the rainfall stations are arranged in climatic districts, both for the eastern and the western interior of the continent, the best rains occur during the "rising phase" of sun-spot activity and the poorest during the minimum phase. In the Northern Territory and Central Australia generally, the best rains occur later, or during the "declining phase," the lag amounting usually to 3 years, or in the case of Daly Waters possibly 4 years. The rainfall response to solar activity of the eastern and south coastal stations is generally so slight as to be almost negligible. For the rainfall increase over the eastern and western interior of the continent during the rising phase of solar activity, it is suggested that since these areas derive their rains almost entirely from air drifts of tropical origin, these must be of greater energy and frequency during this sun-spot phase. For coastal areas the maintenance of the rainfall during the minimum phase may be due to the greater frequency there of coastal cyclones. The increased rainfall in the Territory and Central Australia during the declining phase may be due to longitudinal changes in the loci of the southward tracks of tropical air drifts. The rainfall curves were smoothed by using 3-year means instead of the individual records, thus eliminating the effects of a possible 3-year period. The correlation coefficients of a number of these were computed. The correlations suggest that Bendigo and Daly Waters represent the maximum relations, both direct, but the former immediate and the latter delayed, and it may be that other stations show the double impulse in varying degree. With unsmoothed rainfall curves these two stations give lower correlation coefficients, +0·46 and +0·42 respectively, which suggests the probability of something like a 3-year period in their rainfalls. This is also suggested by breaking up the rainfall records into periods corresponding with those of the sun-spot cycles and taking the means of all the first, all the second, all the third (and so on) years of the cycle. For Bendigo there is for each the mean of six years. These results point to a tendency for droughts to occur every third year except during the rising period of sun-spot activity, which seems to have the effect of a forced oscillation.—J. A. **Smith**: On the graduation of circles. Reference was made to the work of Bird, Troughton, Ross, Ramsay and Swasey in the development of accurate methods of graduating circles.—G. F. **Hill**: Notes on *Mastotermes darwiniensis* Froggatt (Isoptera). After reference to the similarity of the ovipositor of the adult Mastotermes to that of the common American cockroach, the hitherto undescribed egg-mass of this termite is discussed. In all other termites, so far as is known, the eggs are extruded separately. Descriptions are given also of the third-form neoteinic king and queen and the first- and second-form nymphs. The seasonal appearance of the colonising flights and the distribution of this termite in tropical Australia are briefly discussed.—H. B. **Williamson**: Revision of the genus Pultenæa, Pt. iv. Two distinct forms have been included under *P. stypheliodes*, one with alternate and the other with ternate leaves. The former is the true *stypheliodes*; the latter is separated as *P. subternata*. *P. procumbens* is suggested as a low form of *P. stypheliodes* and made a variety of that species. Two new species, *P. trichophylla* from Port Lincoln, and *P. pubescens* from Mt. Gambier and the Grampians, are described.—F. **Chapman**: New or little-known fossils in the National Museum. Pt. xxviii. Some Silurian rugose corals. Four genera are here discussed. Lindstroemia is held to be a well-defined genus, with the genotype indicated by Nicholson and Etheridge's figured *L. columnaris*. Five species are recorded from Victoria, all of which are new. In the presence of a weak bilateral symmetry, some of the species show that the genus has some affinities with the Zaphrentidæ. Cyathophyllum is represented by two new species, from the

Yeringian—*C. cresswelli* and *C. subcæspitosum*, the latter closely resembling the Devonian *cæspitosum* of Devonshire and the Eifel and helping to strengthen the Devonian element in the Australian Silurian. In Spongophyllum there are two new species, one from the Yeringian of Victoria, *S. stevensi*, related to *S. sedgewicki*; the other, *S. shearsbii*, from the Yass beds of New South Wales. The genus Columnaria is represented by a new species from the Melbournian, *C. flemingtonensis*, preserved as a faithful negative mould in a fine ferruginous mudstone.—Miss Leslie Kerr: The lignotubers of Eucalypt seedlings. The lignotubers are embryonic storage organs, and not pathological as was previously supposed. These basal inflations of the stem attain their maximum development in the species inhabiting the most arid areas, while six species inhabiting regions of high rainfall do not develop them.

August 14.—Prof. T. H. Laby in the chair.—E. Kidson: Some periods in Australian weather. Recent work was described in extension of Dr. Braak's theories regarding a three-year period, especially clearly shown in the pressure variations at Port Darwin. Strong evidence of an 18-months cycle in the atmosphere, of opposite phase in eastern and western hemispheres, equivalent to a nutation of the whole circulation system, was adduced. Characteristic annual variations of the velocity, pressure, and latitude of anticyclones were evolved. A high correlation was established between the annual latitude range of anticyclones and sun-spot numbers.—E. J. Dunn: The centenary of Selwyn the geologist.

The Abrams' Cult in Medicine.

IN our issue of June 7 we published an article on "the Abrams' Cult in Medicine" and indicated that the claims made on behalf of the late Dr. Abrams were without scientific foundation. One of the many ridiculous diagnoses made by means of the so-called electronic dynamiser was quoted, and the methods employed by the "electronic reaction Abrams" (E.R.A.) were described. In the July, August, and September numbers of the *Scientific American* there is an extensive report of a committee of experts appointed by that journal to inquire into the actual facts of the case. The committee consisted of thoroughly trained medical and electrical investigators, including such well-known men as W. H. Park, W. C. Alvarez, R. C. Post, and J. M. Bird, with A. C. Lescarboura as secretary. These men have spent a year chasing the elusive methods of electronic medicine. They have interviewed and co-operated with electronic practitioners and experts in the new cult, and the result is disastrous to the reputation of Albert Abrams.

The report of this committee is in what may be described without offence as the characteristic American style—interesting to those on the eastern side of the Atlantic. The authors of the report state that the "Electronic Reactions of Abrams are not substantiated, and it is our belief that they have no basis in fact. In our opinion the so-called electronic reactions do not occur, and the so-called electronic treatments are without value." In another place the committee states that "the entire Abrams' electronic technique is not worthy of serious attention in any of its numerous variations. At best it is an illusion. At worst it is a colossal fraud."

The *Scientific American* committee gives a clear account of the genesis of the Abrams' myth, and shows how the Californian Cagliostro's claim that the basis of life is bound up with the movements of electrons is a question which does not admit of proof. On the electronic basis, however, Abrams invented a mysterious box called a dynamiser for collecting the electronic emanations, and elaborated a portentous system in which diagnoses of the most obscure ills of life were said to be possible, at a distance of thousands of miles, from the emanations given off by a drop of blood on a disc of blotting-paper. Not only the disease of the patient but also the height, habitus, colour, sex, and religion were said to be capable of revelation by the dynamiser—a childish toy which defies all the laws of electrical science. In one of Abrams' own demonstrations he placed in the dynamiser a photograph of a man and foretold his disease as insanity due to syphilis, and on running the electrode across a map of America

it stuck at Stockton, California, which was consequently proclaimed as the patient's address!

By judicious advertisements and newspaper "puffs" by credulous persons and those in quest of sensational material for the press, Abrams' claim to diagnose disease at a distance was soon noised abroad, and Abrams founded a school rich in financial possibilities. He then added to the diagnostic scheme one of electronic treatment, thus providing a wider field for commercial exploitation. New companies sprang up to manufacture the Abrams' dynamisers and oscilloclasts at fancy prices. Schools for training Abrams' practitioners were founded, and a motley array of medical men, osteopaths, chiropractors, and electro-naturopaths hied them to sunny California to sit at the feet of Gamaliel and hear him expound the new science. Within a few years, more than three thousand practitioners of electronism were trained for their life work in the United States alone. They found that there was a rich harvest in dollars, in comparison with which ordinary medical practice was a poor profession.

When one reflects that we are living in the twentieth century, and that both medical and lay people can believe something which has no meaning, it is clear that there is no limit to credulity. There have been great humorists in history, but Dr. Albert Abrams of California must surely head the list. To invent a new form of energy which cannot be tested by any known method except by the five senses of Abrams and his pupils is something of an achievement. To determine the sex of a child *in utero* from a drop of the blood of the father a thousand miles away is asking one to believe a good deal. To explain errors in electronic diagnosis in California by wireless disturbances on the Eiffel tower in Paris or activities on the planet Mars is perhaps reasonable from the electronist's point of view. To expect, however, your fellow-creatures to believe all this nonsense, and to earn vast sums of money by the delusion, may be classed as a form of humour to which our psychologists and mental philosophers have not paid due attention. Although the *Scientific American* committee has exposed the absurdity of Abrams' system, it does not follow that its labours will be crowned with a universal success, for in all probability there will still remain hundreds of genial persons who do not mind paying their dollars to hear the joyous tick-tack of Abrams' oscillating metronome.

We live in an age of science, but it is as easy now as ever it was for the charlatan to impose on the credulity of the public. The penalty of great scientific achievement seems to be that people are ready to accept the most astounding claims, provided they are put forward in the name of science. W. B.

EVEN in these days, people still occasionally to science, or at least to natural science, as subject of purely academic interest, though remark changes have been made during the last thirty y In the lifetime of the present writer it has bee interest to watch the gradual penetration of the met of the natural sciences into many branches of knowle Many subjects, formerly holding themselves mor less aloof, are now permeated by scientific method, work upon lines as scientific (or knowledge-making that is what the word implies) as are those of su science as botany, at any rate, even if not yet of s a science as physics.

The world is, indeed, gradually realising that scie simply means organised and reasoned knowle without which rapid progress is almost impossi Knowledge is good, and organisation is good, and their combination there are opened up possibilitie progress to which we can see no limit. Both kn ledge and organisation are necessary for satisfact and efficient work, yet the combination of the two long looked at askance, probably because it was f applied to subjects that seemed to have little or bearing upon practical life. With the proper org isation of inductive knowledge, general laws of e wider application begin to appear, progress becom more and more rapid as deduction becomes more a more possible.

Such being the case, it is a little difficult to draw line in referring to developments in the British Emp due to science, for which the volumes in question serving as the text. Engineering, the most import of all as yet, must, of course, be considered, and also rapidly growing science of agriculture, which is strong basis of the art of agricultural practice.

Scattered over the four quarters of the globe as it the British Empire has an enormous variety of sources, and there are few things required by mod civilisation which it cannot if needful produce.

st necessity, however, is security of life and of perty, and this scattering of the parts makes the mire more vulnerable, necessitating the keeping up great fleet, in which the application of science nifest in almost every detail.

he second great necessity is an adequate popula- for the various parts of the Empire, and this presents haps the most difficult problem that lies before our smen at the moment; for there is no doubt that ept in the British Isles, in India, and a few West an islands, the population is absurdly inadequate. ralia and Canada with their enormous areas have, n rather less, the other rather more, than two ple per square mile, against 7 in Argentina and Brazil, to take countries of similar sizes and ages. portant though this problem is, however, scientific wledge of the many questions involved is as yet n in the early stages of organisation, and one can cely draw deductions upon which it is safe to act. ence is rapidly entering very largely into the stion, however, with the wonderful discoveries of last half-century in medicine, bacteriology, surgery, t, discoveries which have saved great numbers of s, and have much improved efficiency.

s the population grows, so also must the food-supply, the present condition of that of the Empire affords interesting study. At the headquarters of Empire re is no pretence at growing enough food for the ple—the fact that the British Isles are admirably ated and equipped by Nature for a manufacturing ntry, added to the ordinary laws of supply and nand, have ordained that the population shall out- w the local food-supply, and live largely by export de, obtaining food in exchange. In this exchange, countries of Europe, and the United States, with ir large populations causing a large demand for nufactured goods, and with their nearness to the itish market, have an advantage over most of the Inpire countries, though Canada and others with reasing population are steadily taking an increasing are in the supply of the comparatively non-perishable d-stuffs such as wheat, or of those that can be sent cold storage. The general tendency at the present ne seems to be in this direction, with increased tention at home to the more perishable supplies food, at present largely imported from the ntinent.

The other Empire countries usually grow enough od for their own people, though some, like Ceylon, e strange exceptions, and they have often a fair nount left over for export to Europe or to whatever arket is most suitable and profitable. When the arket is very attractive, as, for example, the British arket in wheat, they tend naturally to make a special business of growing for it. Parts I. and II. of the first of the volumes under consideration, from the able pen of Prof. Ainsworth-Davis, deal with the food of the Empire, with full statistics of production, trade, etc., and place before the reader an organised mass of detailed information upon the subject, from which, by aid of the further necessary equipment of a scientific mind, it is possible to deduce promising lines upon which to act. What at present seems to be chiefly required is the more complete application of science to agriculture, to ensure a greater, more profitable, and more economic yield of the food crops. This is especially needful in Britain itself, in order that the country should produce more food, and thus be more secure in the event of another great war, though it seems unlikely that the country will ever be able to dispense with import upon a large scale, even of the first elements of food, which is all that we are at present considering. In the rest of the Empire, work of this kind is just as useful, inasmuch as it may diminish cost of production of necessities, and thus set free more labour for leisure and luxury.

Now this in fact is what is actually happening all over the world. By the study of pests and diseases, for example, science has rendered, and is rendering, great service to those who suffer from them, and by checking their ravages is thus increasing the yield and profitableness of both plant and animal husbandry. By a proper chemical study, the art of cheap and efficient manuring has become much better understood, thus providing greater increases of yield at less cost than formerly. Similar results have been obtained by the proper study of the feeding of animals. The rise of Mendelism in recent years has enabled us at any rate to make a commencement in the direction of breeding upon scientific lines towards a desired end, instead of merely taking "the gifts the gods provide." Already results are being obtained, for example, with Prof. Biffen's new wheats, that may lead to great developments in the near future. Fruit and vegetable growing, and all other forms of agriculture and horticulture, are similarly receiving close attention at the hands of properly trained men, as are the fisheries and the study of domestic animals.

In the Dominions, on the other hand (as in the United States), the scarcity of labour has tended to make the scientific development of labour-saving one of the most important directions of research, whilst the impossibility of carrying many food-stuffs to Europe in their natural fresh condition has stimulated research into methods of canning and of cold storage, both of them lines in which much work is now being done, and considerable trade springing up.

Not only must the people be fed, but they must in

general be clothed also, to at least the minimum degree prescribed by local custom; and in this connexion the volume upon fibres (Vol. 3) comes in useful. By far the most important fibres for clothing are cotton and wool, and of the latter the Empire produces a very large proportion of the world's supply. On the other hand, the position in regard to cotton is not one in which to sit with folded hands. Of short-stapled cotton the Empire produces the bulk of the world's supply, in India, and with it clothes a great part of the population of that country, besides exporting much to Japan and elsewhere. But of the cotton of medium and long staple, such as is used in Lancashire, the Empire produces less than 200,000 bales, against a world consumption of about 15 or 16 millions, when it ought to produce about 25-30 times as much, and with the falling-off in the supply from the United States, bids fair to get into difficulty.

This position has long been foreseen, and the British Cotton Growing Association was formed more than twenty years ago to deal with the question, but of late there has been added to this body, which has done a very great amount of valuable pioneering work under great difficulty, the powerful Empire Cotton Growing Corporation, which, though not directly a department of Government, but managed chiefly by far-seeing and capable Lancashire business men, received Government aid in an endowment, and in a compulsory cess upon all cotton used in Great Britain. Nothing could show more clearly the strong position that science now holds than does the work of this Corporation, which supports financially the work in many scientific institutions, trains its future workers in science laboratories in England and elsewhere, and in general acts upon what may rightly be called scientific lines.

So old and so long established are the weaving industries, and so entirely do they depend upon mechanical methods, that as yet there has been comparatively little intrusion of scientific methods into them other than in the constant improvement of the machinery.

Leather, upon which there is a volume (Vol. 6), may also be mentioned here, inasmuch as shoes (or sandals) have ceased to be a luxury, and have become a necessity to a great many. The large size of the volume just mentioned, compared with the small size of that dealing with the food-stuffs, prompts the reflection that the work is somewhat unevenly proportioned; the volume dealing with tea, cacao, coffee, and rubber is almost equally large. To return to leather, since the Empire contains about 40 per cent. of the animals which furnish it, there is no reason to fear any shortage.

The people must also be housed, and in this connexion the volume upon timbers (Vol. 2) is useful as indica the resources of the Empire in one of the prin materials used in housing and furnishing. In mos the tropical colonies, and in India, the housing is sin of type varying with the materials that are most rea obtainable locally, for example, bamboo in Mal mud-and-wattle in Ceylon (with a tendency to repl ment by kerosine tins), and the like. But in the w portions of the Empire, with their colder clim housing has become more standardised, and perhaps since the War is there any tendency to a long-established custom, or to invoke the aid scientific knowledge in building.

We may take it then that as the Empire incre in population it will be able to feed, clothe, and h the people without any falling-off from the pre standards, the necessary corollary being fulfilled adequate and economical transport be provided to up its different parts, some of which will provide item, some another.

A country in which the people are merely clothed, and housed, upon the lowest terms (so speak), cannot, however, be called rich, prosperous progressive. The possession of riches implies the po of obtaining the best of everything in the grea variety, and the possession of sufficient leisure education to enjoy travel, art, music, literature, the other adornments of life. The possession of wea that goes beyond this confers little upon its owner power, and it should chiefly be used as investme There is therefore something to be said for the grad diversion of such wealth to the use of the State a basis for the improvement of the position of alike. It must not, of course, be supposed that ma people possess, or are likely in the near future possess, riches enough to command all that has be indicated, but most people strive to obtain as much possible, some in one direction, some in another; a tastes differ.

For this amelioration of the conditions of life, whi has long been going on, and will, it may be hoped, lo continue, many things are necessary, not the lea among which is an extensive exchange of produc between one country and another, involving cheap a good transport. Life would be a poorer thing Britain had we no sugar or spice, no rice, sago, tapioca, no tea, coffee, or cocoa, no rubber, no wi or tobacco, no oil (whether mineral or vegetable), wi its concomitant no soap, no cotton or jute, no go or silver, no bananas, oranges (marmalade), grape currants, raisins, or many other things, to say nothi of our import of many of the basal necessities of li The great dominions and the smaller colonies a equally deficient in many things needful to make l

fortable as judged by our present standards, and ...out the present extensive trade that goes on, life ...ld soon be reduced to very simple terms once more. ...nsport, upon its present efficient lines, has only ... rendered possible by the work of engineering ...nce, and improvement continues to be made almost ...y.

Whilst there is scarcely any country in the world now ...rovided with the comparatively cheap steamship ...nsport, the development of land transport still ...es much to be desired. It goes, as does the former, ...h the development of sufficient trade to make it ... its way, or roughly with the growth of population, ...ugh a tendency is now becoming clearly marked for ...ds and railways to be made in advance, to encourage ...l growth of population, agriculture, and trade. Air ...nsport, which may at any time become of enormous ...portance, need only be mentioned here. An im...tant concomitant of transport is rapidity and ease ...communication. At first dependent directly upon ...former, it has now become to a considerable extent ...ependent of it, as witness the wonderful feats of ...ence in the invention of the telegraph and the tele...one, at first with wires, and now without, the in...tion of "wireless" promising to revolutionise ...world in this direction at some not very distant ...e.

In the provision of what we may term the luxuries, ...t make life more enjoyable, and that give a real and ...gible value to monetary wealth—luxuries that one ... one come to be regarded as necessities—science has ...d a very large and increasing share, which may be ...efly indicated. But it must be realised that all parts ...the question hang together, and that progress in one ...n only accompany progress in another. Progress in ...neral is slow, but every now and then some great ...nius appears, whose invention or discovery involves ...ange in many departments of life.

Agriculture (in the broadest sense), and mining, ...ovide the great bulk of the raw material of wealth, ...t transport, and more or less of manufacture, are ...nerally needed to make it really available for use. ... early days agriculture was (of necessity) conducted ...ainly upon the principle of "grow-what-you-want-...d-consume-what-you-grow." Gradually, with the ...provement of transport systems, a certain amount of ...ecialisation came in, whilst a considerable trade ...rang up in the products of wild trees or plants, which ...uld be collected without cultivation, and were worth ...hile, such as rubber, gutta, cinchona, cinnamon, and ...any other things.

While at first the products of any country were such ... were native to it, this gradually altered with the ...provement of transport, and the useful plants and animals of one part of the world were carried to others, at first often to places quite unsuited to them. Thus, at the present time plants are cultivated for market quite irrespective of their countries of origin, though in a few instances, such as cinnamon in Ceylon, the original country has retained a practical monopoly. Even up to quite recent times there have been striking examples of the success of introduced cultivations in new countries, as witness the rubber boom of a few years ago, and the present extension of cotton in tropical Africa. But this phase must necessarily pass, inasmuch as everything will soon have been introduced into all the countries where it will be likely to succeed. At the same time, the great extensions of cultivation thus brought about have often reduced the profitableness of a cultivation to a very low point. On both counts the aid of science is now being called in, and the next phase of agriculture will be the scientific. It is almost needless to say that science has always had more or less to do with agriculture, for example, by means of the Botanic Gardens maintained in many places; but there is no doubt that its share in agriculture is increasing all the time, so that cultivation may be said to be becoming more and more scientific, both in itself and in its accessories, such as disease-prevention and the like.

While the necessary elements of food have been practically always available in ample quantity, luxury in food continues to increase, and many things once regarded as luxuries are now usually counted as necessities, such, for example, as tea, coffee, cocoa, spices, and tobacco (to call this a food for the moment), to which Vol. 5 is devoted. Improvement in food is due to many things, but chiefly to greater variety of origin (with which of necessity goes the transport to carry it to other places), and to improvement in the actual kinds of animals or plants used. In both of these, but more especially in the latter (by improved breeding), science has had a large share, and will probably have a larger share as time goes on.

Fibres in the same way are being provided from an increasing number of sources, and their uses are being extended, while at the same time, by the application of science to cultivation and treatment, the yield is being increased, and the quality improved. The great need before the Empire at the moment is to increase the production of good cotton within its boundaries.

New timbers, too, are being discovered, and new uses for timber, but there is still much room for the application of scientific method. If some way of exploiting the mixed forest of the tropics could be discovered, which would place at the disposal of mankind its great riches in many valuable timbers and other products, a great service to humanity would be done.

P I

To the achievements of science in adding new amenities to life one cannot refer in detail; let it suffice to direct attention to such things as the telegraph and the telephone, to rapid and comfortable travel by steamboat, by rail, by road, by the motor and the aeroplane, to wireless communication (including listening-in), and to innumerable other inventions, only rendered possible by scientific discovery and its application.

The problem now, and probably always, before us, is to increase the supply of the luxuries of life, and make them more available to every one, while at the same time cheapening the cost of production of the necessities and setting free more labour to be devoted to the former. At the same time, for a long while to come, we must allow for a continually increasing population. There are obviously many factors that come into this problem, including, for example, increased efficiency—best brought about perhaps by the careful application of statistical and other science to the problem in hand and by better education—and greater and more economical application of power derived from coal, from oil, from water, and from other sources as yet untapped, and only to be tapped by the careful application of science; and many other factors which determine human progress.

For such work as now outlined, haphazard methods are of little or no use; we require our knowledge systematised and organised to the highest degree possible at the moment. It is for this reason that one welcomes the publication of such volumes as those under consideration, appearing at the same time as the great exhibition at Wembley, which lay before us a clear picture of the actual resources of the Empire, so far as they are at present known. That many more remain to be discovered by the aid of scientific research need scarcely be said of course, though one must in passing note the interesting fact that in agriculture, at any rate, the knowledge and skill of the white man has added comparatively few products, and none of first-rate importance, to those which were known in prehistoric days. Economic botany, which requires its main assistance from organic chemistry, is as yet too much of a chaos of facts, with few general laws that we can yet see that underlie them, to be of any use in making predictions. This, however, will doubtless be altered in time, and with the wonderful improvements in breeding that are taking place as a result of Mendel's work, we may look forward to the future breeding of economic plants "to order." The heyday of empirical practice has passed, and the future appears to lie with scientific (or organised and classified) knowledge. It is for statesmen to see that the power which this knowledge gives is used for the well-being of mankind.

Rejuvenation.

Rejuvenation and the Prolongation of Human Efficiency: Experiences with the Steinach-Operation on Man and Animals. By Dr. Paul Kammerer. Pp. 25 (London: Methuen and Co., Ltd., 1924.) 8*s.* 6*d.* ne

WHEN a new development in science has pr vided the low comedian with material for je and the popular author with a plot, when from t biassed misinterpretation of the journalist it appea that a discovery has been made that must revolutioni the life of the individual and of the community,—th it is high time that some one with a training in th particular branch of science and in scientific metho and with a literary ability that enables him to interpr to the man-in-the-train, should give a popular presen ation of the facts and the theories based upon then so that all those who seriously seek information on th subject can glean it. A book in English dealing wit the operative methods of achieving rejuvenation an giving in a legitimately popular form a critical revie of the work of Steinach, Voronoff, and their followe has, therefore, been expected for some time; and th is attempted in the volume before us.

The interested general public wants to know curre biological opinion concerning the cause of ageing an death; it wishes to learn whether and how one ca be compensated and the other postponed. Is agein the result of the accumulation of the effects of aut intoxication, of inefficient excretion of the deleterio end-products of metabolism? Is one of the function of the glands of internal secretion to purify and vitalis the whole body; and are these glands so inte dependent that if one comes to function less efficientl the whole endocrine system is thrown out of gear Can the adequate functioning of the endocrine syste in these circumstances be re-established by operativ measures that repair the weak link in the endocrin chain? It is on the assumption that the answer t all these questions is in the affirmative that rejuvena tion has been attempted deliberately by injection o extracts, by the implantation of glandular tissue, an by the ligation of the deferent duct of the testis in th male.

It is claimed that specific and demonstrably bene ficial results follow such treatment in the huma subject, in farm stock, and in the laboratory mammal It is desirable that this claim should be examined mos carefully, particularly in the case of the human, fo here it is always necessary to allow for the effects o suggestion. There is plenty of evidence available fo this examination, and of such a kind as to lead to th conclusion that it is possible in suitable cases to achiev rejuvenation.

s for the methods to be employed, that of injection uch extracts as are available at present is utterly rustworthy; for the implantation of grafts an adete supply of human or simian gonad is required, this is not easily maintained; unilateral ligation he deferent duct of the male, on the other hand, is imple operation that has often been performed, ugh Steinach was the first to do so for the dee purpose of bringing about the rejuvenation cts.

f the Steinach operation is followed by demonstrable provement in the general well-being of the individual, l there is considerable evidence which seems to show it it is, then this operative procedure must quickly l its way into human and veterinary surgery. For mple, it would mean much to the stock-breeder to able to get another year's crop of offspring from a ous sire.

Rejuvenation in the female is an altogether different tter. Not nearly so much work has been done in s field. The most promising method would seem be that of irradiation of the ovaries with X-rays; s leads to sterility, but at the same time, it is claimed, rejuvenation.

The whole question is being followed with the greate interest by the medical man who has to prepare nself for the giving of advice, and by the patient who inclined to seek it. For the former there are the dical journals; for the latter there are the newspers, and now we have Dr. Paul Kammerer's survey the subject.

Reading this book, one gains the impression that it a literal translation of a German manuscript into an nericanised English by one who is not a physiologist. is full of phrases that startle and hurt both the man science and the grammarian, and about it there is too much that savours of advertisement. It is true at the facts concerning the methods and the results the operative treatment of old age will be found in e book, but far too frequently they are completely scured by a painful misuse of the English language, a lack of knowledge of the author's meaning, and norance of physiological terminology on the part of e translator.

The book suffers also, and severely, from the o strenuous effects that were made to present e subject in a popular form: there is a degree of opularity offensive to the professional scientific orker, who cherishes the dignity of his science. The bject is a most fascinating one, for throughout the ges man has yearned for immortality and has ever hemed to achieve it. A most excellent popular book ould be written about it: in our opinion, it still emains to be written. F. A. E. CREW.

Our Bookshelf.

Time Measurement: an Introduction to Means and Ways of Reckoning Physical and Civil Time. By L. Bolton. (Bell's Natural Science Series.) Pp. viii+166+8 plates. (London: G. Bell and Sons, Ltd., 1924.) 6s. net.

IN this book the author has aimed at giving the rudiments of time measurement to readers possessing no previous knowledge of the subject. The first forty pages deal with the nature of time measurement and of the more prominent natural cycles (the year, the day) suitable for the purpose of measuring time. To assist the reader towards an exact understanding of the astronomical terms involved, the author insists upon the use of the globes and the armillary sphere, and describes in full detail a cheap home-made example of the latter instrument.

Early time-pieces (water clocks, sand clocks, and sundials) for subdivision of the day by artificial means are next briefly described. This is followed by a chapter on weight-driven clocks of the thirteenth and fourteenth century, descriptions being given of De Vic's clock (*c.* 1370), the Wells clock (*c.* 1393), and the Dover Castle clock. Photographs are shown of the two latter examples, which have for many years been exhibited in going order in the Science Museum at South Kensington. The author directs attention particularly to this chapter and a later one dealing with striking mechanisms, pointing out that though of rough workmanship, these early machines were anything but crude in conception, and expressing the hope that "the reader who studies these chapters will be left with an enhanced respect for the attainments of the Middle Ages."

Other chapters deal with the work of Galileo and Huygens; Hooke, Graham, and Harrison; driving mechanisms; watches and chronometers; electric clocks; Greenwich mean time; the calendar. Though the few short biographical notes woven into the text in some cases throw unduly into relief certain personal imperfections (Hooke—"unlovely character," "unhappy miser," "stinginess"; the two Scaligers—"not entirely reliable in personal matters, and altogether they seem to have been unpleasant people to deal with"), the book as a whole deserves commendation as a good introduction to its subject, especially for the class of reader for which it is intended.

Sunshine and the Dry Fly. By J. W. Dunne. Pp. v+136. (London: A. and C. Black, Ltd., 1924.) 5s. net.

MR. DUNNE'S book will be read with great interest by the devotees of dry-fly fishing, if only for its unorthodoxy, amounting almost to heresy, in its attitude to the works of Halford, hitherto regarded as the standard works on the art of dry-fly making, and slavishly used by most anglers. The author objects that Halford obtained the colours of his dry flies from the natural flies seen under wrong conditions of light, and that his record of colour is therefore erroneous. Mr. Halford placed the natural flies on their dorsal surfaces in a white saucer and allowed strong light to fall on their ventral surfaces, and in this way sought to obtain the colours of the fly as seen by the fish. As Mr. Dunne

points out, this method reduced the light showing through from the back of the fly and increased that reflected from the ventral surface, with the result that Halford's colours are darker than they should be. Further errors crept in from the use of preserving fluids, which materially altered the colour of the natural flies preserved in them for copying purposes.

Mr. Dunne seeks to remedy these two sources of error. He avoids the use of preservatives for his models, and studies their colour by placing them on a glass plate in their natural position, dorsal surface uppermost, and examining them from below against the sky, thereby reproducing more closely the conditions under which the fish sees them. From this point of view the author has reviewed Halford's work and produced a new series of dry-fly patterns, full directions for the tying of which are given in a valuable appendix. He has also experimented with the view of imitating more closely the translucence of the natural models, and claims to have succeeded even beyond his hopes. Mr. Dunne's book is vigorous and stimulating, and deserves careful study by his fellow-sportsmen.

A Dictionary of Applied Chemistry. By Sir Edward Thorpe; assisted by Eminent Contributors. Revised and enlarged edition. Vol. 5: Oxygen to Rye. Pp. viii+722. (London: Longmans, Green and Co., 1924.) 60*s.* net.

THE fifth volume of the new edition of Thorpe's "Dictionary of Applied Chemistry" has recently been issued, covering the section from Oxygen to Rye. This section has been enlarged from 570 to 722 pages. The most important additions are a new article on "Electrical Precipitation" by Dr. H. J. Bush, covering 17 pages and containing 20 figures, and a new article on "Refractories" by Dr. J. W. Mellor, which covers 10 pages and contains 6 figures. The article on paints has been expanded, in part by a fuller discussion of white pigments, including the debated question of regulations for the use of lead paints, and a new paragraph on fillers and extenders. Prof. J. F. Thorpe's article on phenols has grown from 10 to 13 pages, and Dr. Hewitt's article on quinones from 45 to 50 pages. Still more considerable expansion is found in the article on photography, which has grown from 35 to 51 pages; and the 10-page article on radioactivity now covers 23 pages (under the heading of radiology), mainly as a result of the addition of a 12-page section on X-ray spectroscopy, over the initials of Dr. E. A. Owen. Only one important example of shrinkage has been detected by the reviewer, namely, an omission of 7 pages on Scheele's method of preparing phosphorus, the details of which are now disposed of in two lines, by a statement that "Full details of this practically obsolete method were given in the last edition of this work." Chemists and others will be glad to add the new volume to their shelves, and will find that the revision has added substantially to its value.

Algebras and their Arithmetics. By Prof. L. E. Dickson. (University of Chicago Science Series.) Pp. xii+241. (Chicago: University of Chicago Press; London: Cambridge University Press, 1923.) 2.25 dollars.

THE existence of various systems of algebra, in which the commutative and associative laws of ordinary algebra are not assumed to be valid, has been known to mathematicians since Hamilton expounded his theo of quaternions. Such systems of non-commutati and non-associative algebra, based on a set of postula consistent with itself, are now termed *linear*, and t general entity of a linear algebra, a hypercompl number, marks the final stage in the evolution number. The first half of Prof. Dickson's book e pounds the theory of linear algebras and explains t terminology adopted in their classification. On moderate mathematical attainments in the reader a assumed, and, apart from the development of t subject-matter, the book will be of great value to tho interested in the foundations of mathematics.

The theory of arithmetics of algebras has bee surprisingly slow in its evolution. Naturally, t arithmetic of quaternions received attention first, successful theory being obtained by Hurwitz in 189 In passing to the arithmetic of any rational algebra t first main difficulty lies in rightly defining the integr elements. The early attempts of Du Pasquier soo led to insurmountable difficulties which are discusse by Prof. Dickson. By adopting a new definition t author has been able to develop a new arithmetic theory, valid and self-consistent in any ration algebra. As yet the theory is only in its infancy: leaves open a promising field for the research worker.

W. E. H. B.

The Book of the Wandle: the Story of a Surrey Rive By Dr. J. M. Hobson. Pp. xii+196+16 plate (London: G. Routledge and Sons, Ltd., 1924. 10*s.* 6*d.* net.

THE short Wandle river is historically of some import ance, and Dr. Hobson has honoured it by writing a boo about it. Owing to its rapid fall it has worked number less mills from time immemorial, and we should hav wished to have learned more about it as a source o water-power, such as that given by Close in connexio with the Southampton Itchen. Otherwise we hav in this book a comprehensive account of the Wandle' genesis and geology, its fauna and flora, its industrie and its many literary and other associations. Writte in popular style, it contains much valuable information collected mostly from the Proceedings of the Croydo Natural History Society, which is to be congratulate on the valuable work that its members have done.

The author rightly points out that intermitten bournes often show the extended courses of present-da dwindled rivers, and the Croydon Bourne shows th former course of the Wandle. If ever it came ove what is now Pebble Coombe may be doubtful, althoug Chipstead valley, Smitham Bottom valley, and Cater ham valley no doubt once fed the river. As the valley from Marden Park furnishes so much water to the Bourne now, sufficient importance perhaps has not been given to this branch of the former Wandle, as we should imagine that this branch was of later persistence than that from Merstham, although we recognise that the latter pass is a good deal lower than the Marden Pass.

We may point out that a vallum of the Romans was not necessarily made of stone, although Dr. Hobson thinks that such places as Walleton (Wallington) derive their names from the "Welsh," who were left in possession of them by the Anglo-Saxons. The book is well illustrated, and is full of information relating to the wide area drained by the little river which it describes.

Manual of Land and Fresh Water Vertebrate Animals of the United States (Exclusive of Birds). By Prof. H. S. Pratt. Pp. xv+422. (Philadelphia: P. Blakiston's Son and Co., 1923.) 6 dollars.

The naturalist frequently finds that to learn to identify species is a most difficult task, and yet nothing is more important to his work. He finds that species are not separated merely on shape and colour, but on structural peculiarities which frequently are connected with particular habits. This is especially the case in vertebrate animals, which in Great Britain, with its very limited number of forms, may be identified in a haphazard manner by elimination. This is impossible in a country where different climatic areas interdigitate and where there are many species, as the United States, which for the purpose of the naturalist is a continent. Here Prof. H. S. Pratt "fills the bill" by his "Vertebrate Animals of the United States," which, however, omits its birds. A short account of each group is given, the anatomical features dividing it up into sub-groups and families being usually illustrated. Where necessary, special features for families are described and then follow keys to the genera, descriptions of the same and keys to their species. The whole closes with a good bibliography and a glossary of technical terms. The short descriptions of each species, with mention of their geographical distributions and habitats, are excellent, and the tabulation of the sub-species most useful. We learn that there are about 600 species of freshwater fishes, 70 of newts and 61 of frogs and toads—we are given a key by which their tadpoles and eggs can be identified—300 reptiles and a wide series of mammals belonging to 9 orders. We characterise this publication as a book for ready reference, such as should be on the shelves of all American naturalists.

Automatic Telephone Systems. By William Aitken. Vol. 3: Large Multi-Office Automatic Systems; Semi-Automatic Working; Miscellaneous Systems; Lay-out and Wiring; Power-Plant, Traffic. Pp. xv+239. (London: Ernest Benn, Ltd., 1924.) 55*s.* net.

The Strowger Director System of automatic telephony is the system which, after very careful consideration, has been adopted by the British Post Office. It is manufactured by the Automatic Electric Company of Chicago and the Automatic Telephone Manufacturing Company of Liverpool. This was the system which the author described in volume i. of this work. In the volume now before us he discusses large "multi-office" automatic systems and semi-automatic working. Practically all the important systems which are in use, or are nearly ready to be brought into use, are described. The work will be of help to experts. Standardisation is still a long way off. On the Continent the rotary system with switches for 500 lines is popular, and in the United States the panel system is widely used. The author discusses the question of metering calls. In the United States, as a rule, with automatic systems, the calls are not registered. This saves time, and the plant is therefore more efficient. In Great Britain, meters have always been considered necessary because of the introduction of the message rate system. More complicated systems of tariff are, however, being proposed, but before being adopted it will be necessary to convince the consumer that they are equitable.

The First Days of Knowledge: as Narrated quite simply for Young Readers. By Frederic Arnold Kummer. (*The Earth's Story*, Vol. 2.) Pp. 314. (London: Hodder and Stoughton, Ltd., 1923.) 7*s.* 6*d.* net.

This is the second volume of a series of three called "The Earth's Story," of which the first was "The First Days of Man." In a preface to parents, the author explains that his object is to place before young readers a picture of the growth of civilisation in a form which will appeal to the imagination, stimulate thought, and at the same time link up with previous knowledge. This volume, after two introductory chapters, begins with the discovery of bronze; but in dealing with the growth of civilisation from that point onward the treatment is by subject and not chronological. Certain typical inventions, weaving, the water clock, the discovery of silk, irrigation, writing, and so on, are taken one by one and treated imaginatively and, on the whole, accurately. The chapter on religion might not perhaps pass the strict critic in all its detail, but this is perhaps out of deference to young readers—or their parents. It is, however, a little disconcerting to find Constantinople situated in Asia Minor.

Plane and Solid Geometry. By Prof. Walter Burton Ford and Charles Ammerman. Edited by Earle Raymond Hedrick. (Mathematical Texts Series.) Second revised edition. Pp. xi+356+xxviii. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1923.) 7*s.* 6*d.* net.

This is a second edition of a pleasant book. There is nothing very startling in the treatment or sequence, except that the "Pythagorean Theorem" is artificially postponed, apparently so that the authors might give an alternative proof based on proportionals. This is a mistake, because Pythagoras's theorem is the one thing that beginners in geometry get excited about, and its place is as early as is consistent with logical presentation. The alternative proof could have been inserted all the same.

The solid geometry is particularly well done, and the solid diagrams are very realistic. There are numerous applications to practical problems of life and of science, a brief historical sketch, and some useful tables.

S. B.

Cancer Research at the Middlesex Hospital, 1900–1924: Retrospect and Prospect. Compiled by members of the Staff of the Hospital and Medical School and issued by the authority of the Cancer and General Research Committee. Edited by W. Sampson Handley. (Published for the Middlesex Hospital Press.) Pp. ix+90+9 plates. (London: John Murray, 1924.) 3*s.* 6*d.* net.

This small work gives an account of the work on cancer at the Middlesex Hospital, particularly from 1910 to 1923, and incidentally since 1792, when Mr. Samuel Whitbread first endowed wards for the reception of cancer patients, who could remain "until relieved by art or released by death." The record is one of general progress at the Middlesex Hospital, and the book seems to be designed for the lay reader instead of the scientific worker. The financial needs of the cancer department are emphasised in a special chapter.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Physical Nature of Verse.

VERSE as it comes from the speaker consists of currents and vibrations of air in front of the mouth, and of vibrations that are transmitted outward. All that passes from the speaker to the hearer is contained in the air vibrations. The first step in the study of verse must be the purely physical one of registering and analysing the air-vibrations.

The first investigation of this kind was made at Yale University by tracing off a gramophone record of *Cock Robin*. On a gramophone disc the speech vibrations are contained in the sidewise movements of a groove that runs around the surface of the disc. The disc is placed in the apparatus and rotated very slowly. A steel point follows all the movements of the groove. A long lever attached to this point records these movements with a magnification of 300 times on a moving strip of paper. The line on the paper thus gives an immensely magnified image of the air vibrations.

In the speech tracing the lengths of the sounds are measured and expressed in thousandths of a second; this gives the durations of the sounds. In the vowels the long vibrations register low tones, the short vibrations high tones. By measuring the lengths of the vibrations the pitch of the tone in the vowels is obtained. The amplitudes of the vibrations of the vowels are also measured: this gives some indication of the relations of loud and soft. The results for the first three lines are given in the accompanying table. The first line gives the sounds in the ordinary spelling; the second gives the duration of each sound. The third indicates the average pitch, and the fourth the maximum amplitude. The last line gives the impression on the ear.

	Wh	o	k	i	ll	ed	C	o	ck	R	o	b	i	n ?	
Duration in $\frac{1}{1000}$ sec.	10	189	119	154	74	0	53	126	101	74	140	49	56	74	770
Average pitch		333		555	555			238			186		179	179	
Amplitude		4		6	1			5			5		3	2	
Judgment		strong		strong				weak			strong		weak		

	I	,	s	ai	d	th	e	sp	a	rr	ow,
Duration in $\frac{1}{1000}$ sec.	452	210	0	105	81	32	84	291	170	11	294
Average pitch	55 to 250			189			189		189		192
Amplitude	7			5	1	1	2		5	2	6
Judgment	strong			medium			weak		strong		strong

	W	i	th	m	y	b	ow		an	d	a	rr	ow	
Duration in $\frac{1}{1000}$ sec..	108	60	56	74	291	140	490	11	382	120	189	39	331	420
Average pitch	189	476		179	179		143		189	189	194		143	
Amplitude	2	4	1	1	5		4		2		3		6	
Judgment		strong			strong		strong		medium		strong		strong	

The first sound *Wh* is almost inaudible and can scarcely be found in the curve. The second sound begins with small waves, but rises rapidly to an amplitude of 0·4 mm. It has a rather high average pitch of about 333 and is the longest sound in the line. The curve corresponds to the judgment *strong*. The *k* with a duration of 0·119 sec. is the longest consonant in this line, that is, it is also a strong sound. The *i* is still louder and higher than *o* and is almost as long. The *ll*—short and soft as always—has a high pitch, and is therefore strong. We thus find four strong sounds, one after the other. The whole region is justly to be called a raised portion or a hill in the curve of energy.

Then follows a valley. The *C* is short. The vowel *o* has a somewhat long duration and good strength but falls about an octave in pitch. The following *k* has a medium length.

The second hill is marked specially by the length and strength of the vowel *o*. The pitch conforms to the melody of the whole sentence, which begins high and then sinks. The last valley contains the short low and weak vowel *i* and the quite similar *n*. A long pause follows.

The second and third lines are analysed in a similar way. The results show that the verse is to be considered as a flow of speech of varying energy so adjusted that regions of greater energy alternate with regions of less energy. The regions of greater energy are louder, have longer sounds, and are higher in pitch. The curve of energy is approximately as shown in Fig. 1.

The next investigations were of a graphic record of *Somebody said that it couldn't be done*. The analysis showed that a fourth factor of energy is to be added, namely, precision of enunciation. The regions of greater energy show more precise enunciation in contrast with the regions of less energy with negligent enunciation.

In order to express the rhythmical effect of verse we can use a concept familiar in physics. The centre of gravity of a body is a point in which the entire mass of the body can be considered to be concentrated for the purpose of investigation. The centre of gravity is an example of a centroid of forces, a

ɔ ept familiar in mechanics, magnetism, electricity,
t
pplied to verse the centroid will represent the
u of all the factors—intensity, pitch, duration,
r ision of enunciation—as concentrated in a point.
n varying course of speech energy there will be a
ɛps of points, each of which will represent a moment
greatest energy.
he simplest English poetical line consists of a
ntity of speech-sound distributed so as to produce

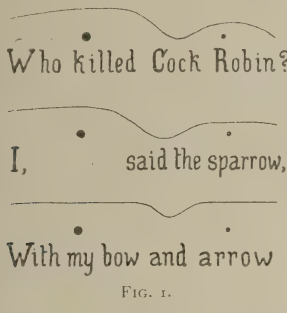

FIG. 1.

a effect equivalent to that of a certain number of
p nts of emphasis at definite intervals. With this
v w of the nature of English verse all the stanzas of
ck Robin can be readily and naturally scanned
a having two centroids in each line. The line
Somebody said that it couldn't be done contains four
centroids.
To the speaker and the hearer the flow of verse may
t treated in its rhythmic effect as a series of
centroids.
A more elaborate study has just been made of the
st line of Hamlet's *To be*. The factors contributing

	T	o	b	e	or	n	o	tt	o	b	e	th	a	t	i	s	th	e	qu	e	s	ti	o	n
Slowness			+	+	+			+		+	+				+				+	+	+	+		
Loudness					+		+				+							+		+	+			
Pitch					+		+				+							+						
Precision	+		+			+		+		+		+		−		−	−		+		+	+		
Energy	Strong					Weak	Strong		Weak	Strong		Weak			Strong		Weak		Strong				Weak	

ɔ greater energy are found to be: (1) Increased
owness of sound change (longer sounds); (2) in-
eased loudness; (3) raised pitch; (4) increased
recision of enunciation. The neighbouring table
ndicates by + the presence of these factors at the
uccessive phases of the record. The positions of the
entroids have been worked out with some precision.

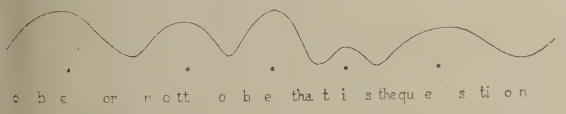

FIG. 2.

he distribution of the current of energy with the
ositions of the centroids is indicated with some
pproximation in Fig. 2.
These investigations of verse show that it is purely
matter of rhythm; it has no metre. The usual
cheme of prosody with feet, syllables, iambus,
rochee, etc., is a fantastic fabric of fancy without
he faintest foundation in fact.

E. W. SCRIPTURE.

University of Vienna.

A Possible Origin of Contracted Burials.

No explanation why the people of the palæolithic and many succeeding ages adopted the custom of always burying their dead in the contracted position has yet been universally accepted by archæologists. The reason given by some is that this is the sleeping posture; that the deceased had been thus trussed (by cords which have perished) to prevent his getting up inconveniently to haunt the upper world; or that it was to economise grave-yard ground—of which by the way there could have been then no scarcity, since there were no cemeteries. A larger body of opinion holds that this position was adopted because in being that of the infant during gestation, the dead was being symbolically returned to the womb of Mother-earth. The latter of these suggestions seems to me to credit prehistoric peoples with more knowledge than they were likely to possess; for how many even of our own uninstructed in gynæcology are aware of the embryonic position? Had palæolithic man—who inaugurated the custom—possessed that knowledge, ought he not to have buried his dead in the final posture of gestation—head downwards? Nor have we any authority for believing that the idea of the dead returning to the womb of earth ever at that early period entered his imagination. There occurs to me another possible origin for the custom.

In New Guinea I have seen many natives in sleep and during sickness; they invariably lay—generally on the right side—with their legs drawn up towards the chin; and when ill, close to a warm fire with the hand supporting the head on a wooden or other pillow. It is well known that this attitude affords instinctively the best relief to a sufferer from abdominal or thoracic pain. I witnessed few burials, but I was a close observer of one interesting and touching spectacle. When at anchor in February 1887 in Milne Gulf, a few hundred yards south of Wagawaga, my attention was arrested by the sound of loud and prolonged wailing proceeding from the village. Some hours later a small canoe put off from it heading towards our anchorage, opposite which (I then observed) a grave had been freshly dug a few yards from the strand.

The canoe, containing a figure seated in the bow and another in the stern, was slowly propelled from the stern by a youth wading in the shallow margin of the sea, while a crowd of villagers accompanied it along the shore giving utterance to piercing and woeful cries of *kaione* (adieu). I had a boat lowered and drew in towards the place of interment. As the canoe approached I could see that the figure in the stern was the wailing mother, and that in the bow an elderly man (the father?) who supported between his legs and against his chest the body of a woman (his daughter?) in a closely contracted attitude, her folded arms resting up against her breast. She was nude except for a fine many-tinted petticoat (*kuri-kuri*) such as is used on festive occasions, and a costly nose-pencil.

On the funeral bark reaching the landing spot, the

body was gently lifted out with demonstrations of affection by four men. As they bore it towards the grave, which was more or less circular in shape and some 4½ feet deep, I could clearly see that the cadaver, without any cords or bindings whatever around it, was still held by rigor mortis in the attitude in which it had died. The body was deposited in its last resting-place in this sitting attitude without any unflexing of its limbs. Over it were laid several grass petticoats, but no other grave furniture so far as I observed, before the earth was filled in.

It seems to me not improbable that where among primitive peoples the dead were not retained long above ground after breathing their last, the contracted position, in which Death usually overtook his victims, stiffening limb and muscle in that attitude by the rigor mortis—a rigidity requiring force to abate—came to be adopted as the natural, if not magical, position for sepulture (whether laid on right or left side or set erect) rather than from any idea of the deceased's position when an embryo, or of "his returning to the womb of earth."

HENRY O. FORBES.

Deanway, Beaconsfield, Bucks.

The Choice of Wave-lengths for Achromatism in Telescopes.

DURING the past summer, in the Transactions of the Optical Society, Mr. J. W. Gifford has directed attention anew to the question as to the two wave-lengths most suitable for achromatising telescope objectives. Mr. Gifford has constructed telescopes in which the paraxial focal length for the D and E lines is the same, and, judging by the performance of such objectives, he considers such a choice superior to the more customary choice of the C and F lines. By a different path I have been led to a similar judgment, at least for telescopes of large aperture.

It is the purpose of this note to show that it is possible to meet the objection, which was made in the discussion, to the closeness of the D and E lines, and also to indicate certain relations which exist between the wave-lengths selected for achromatising and the type of achromatisation which results. The results are for a thin contact pair of hard crown and dense flint, and are deduced with the aid of Hartmann's interpolation formula.

The result of making the focal length the same for two different wave-lengths is to make the focal length a minimum for some wave-length intermediate between these two. On the blue side of this minimum the focal length increases more rapidly than it does on the red side, and as the wave-length of the minimum is made greater, the curve which represents the variation in focal length is made noticeably more flat. From two such curves with minimum wave-lengths of 550 and 560 millimicrons respectively, the data which is represented on the accompanying diagram (Fig. 1) was obtained.

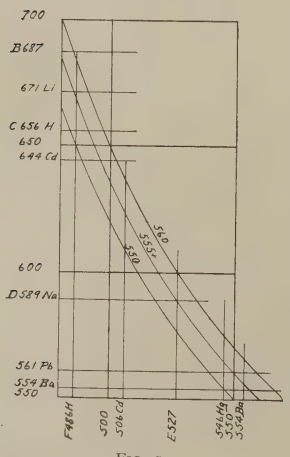

FIG. 1.

On the diagram the curve marked "560" represents all possible choices of wave-lengths which can be used to bring the minimum focal length of the achromatised doublet to a wave-length of 560 μμ. If, for example, one wishes to use the E line and to have the minimum at 560, then one must make the focal length the same for 527 and for 600 μμ. Or, the choice of B and F for achromatising will make the wave-length of minimum focal length just a trifle greater than 560 μμ. In a similar manner, the curve "550" represents all possible choices of wave-lengths which will give the value for the wave-length of the minimum focal length. The intermediate curve, marked "555+", is drawn with the same form as the other two and passes through the point of intersection of D and E. This curve, then, represents the possible combinations of wave-lengths which will be equivalent to the combination of D and E.

Evidently the red lithium line and the F hydrogen line will give very nearly the same result as the combination of D and E, and there does not seem to be another convenient combination which will so serve. However, hydrogen tubes are easily obtained, and the lithium coloured bunsen flame can be maintained for hours at a time by wrapping around the burner a small square of paper which has been previously soaked in a solution of lithium chloride and then dried, feeding the paper slowly up into the flame as it is burned away.

I may add that the aberrations should be corrected for a wave-length in the neighbourhood of that for which the focal length is a minimum. If the hydrogen tube be contaminated with a little mercury, it will furnish the mercury line at 546 μμ, by means of which a value of the index of refraction could be obtained not differing greatly from that at the minimum.

Lake Victoria and the Flow of the Yala River.

WITH considerable diffidence I venture to offer an explanation of the diurnal current change described by Dr. G. D. Hale Carpenter in NATURE of August 30, p. 311. In equatorial regions a twelve-hourly barometric oscillation attains its maximum amplitude of approximately 0·9 mm. of mercury. The maxima occur daily at about 9.10 A.M. and P.M. Thus, in the absence of major barometric fluctuations, the pressure is on the decrease from about 9 A.M. until early in the afternoon at a time corresponding approximately with the time of reversal of the current. It follows that the lake level will be rising during this period, and hence an overflow into the deltaic marsh. The volume of river water entering the swamp should be sufficient to account for the reversal occurring about one hour previous to the time of the barometric minimum.

A second factor that should augment this effect is differential evaporation between lake and swamp. The shallow water of the latter would probably grow warmer during this period and lose more by evaporation than the deep water of the lake.

Further information as to the behaviour of the current during the night—the time of the diurnal rainfall (if this be regular) and the time thereafter when the river level rises—might materially assist in solving the problem.

NORMAN L. SILVESTER.

Aber, Cavendish Ave., Finchley, N.3.

WITH reference to Dr. Hale Carpenter's letter (NATURE, August 30, p. 311) on the subject of Lake Victoria and the flow of the Yala River, the following considerations occur to me. There is a fairly regular diurnal fluctuation in the waters of the lake. At the

el of the Kavirondo Gulf the average level is a few es higher in the afternoon than in the morning. the open shore of the lake at Entebbe the varia- is naturally smaller, but the figures given by Dr. penter (which appear to be in metres) show a trace f. I attributed this variation to the alternation of l and lake breezes, which drive the water away n the shore during the night and early morning and ards the shore during the afternoon. From this or alone one would expect the direction of flow ween the Yala swamp and the lake to be from the mp in the morning and towards it in the afternoon, the reverse of that found by Dr. Carpenter. If channels between swamp and lake are short and p, there might be a regular circulation of the water. diurnal variation of temperature in a shallow mp is much greater than that in the main body of e water. The swamp water cooled during the night ld flow towards the lake as a bottom current and ld be replaced by a surface flow from the lake to swamp, the latter only being observed by Dr. penter. In the afternoon the heated swamp waters ld flow towards the lake as a surface current and cooler lake water would form the bottom current. f this solution is not tenable owing to the length or llowness of the channels, the problem becomes re difficult. Mr. Silvester suggests that the ernation of flow is due to the semi-diurnal wave of ssure. This pressure variation, being approxi- tely equal over both lake and swamp, could not press one relatively to the other unless there is some tor peculiar to either lake or swamp. The only h factor that occurs to me is the presence of gases h as are usually found in the mud of a swamp. The gh pressure and low temperature of the morning uld decrease the volume of the gas and lower the el of the swamp waters. During the afternoon the w pressure and high temperature would increase the lume of the gas and raise the level. The production gas should also be greater during the day, while ing to the vertical circulation, the loss to the air ay perhaps be greatest at night. The effect would aided to some extent by the thermal expansion of te swamp water due to its greater range of tempera- re. I do not know enough about the volume of gas nerated by a tropical swamp to say whether it is fficient for a reversal of the direction of flow in this anner. Differential evaporation could not solve the oblem, as its effect would be, not only very small, t in the wrong direction. C. E. P. BROOKS.

Analytical Sound Records.

THE compound resonators exhibited at the nversazione of the Royal Society in June last have roved useful for obtaining photographic records of usic and speech which clearly exhibit their con- ituent frequencies. Fig. 1 is a record of a scale

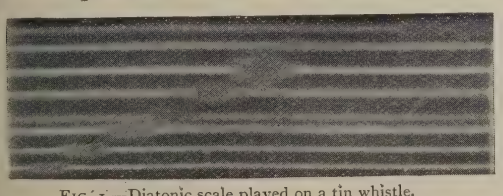

FIG. 1.—Diatonic scale played on a tin whistle.

layed on an ordinary tin whistle, which, contrary o popular opinion, is known to produce nearly pure otes free from overtones. It will be noticed (1) hat there is no overlapping of the notes, each note, when sounding, leaving all the resonators undisturbed except the particular resonator tuned to it. This applies even where the interval is only a semitone; (2) the sounding of a note does not affect the resonator an octave below or above. This observation settles a point in resonance concerning which, I believe, there has been some doubt hitherto.

Fig. 2 shows a record obtained by playing an air

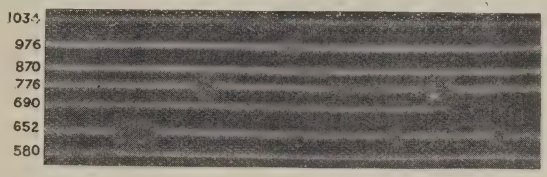

FIG. 2.—"There's no place like home" played on a tin whistle: seven resonators covering the diatonic scale.

on the whistle. It will be seen that the response of the various resonators is very quick, requiring not more than 0·05 sec. for its full establishment. The slight longitudinal overlapping observed in some notes is merely an effect due to the fact that the patches producing the lines are elongated in the direction of the lines themselves, in order to increase the illumination. The high damping factor of the mica reeds produces an equally instantaneous cessation of the note picture when the note ceases to sound. It will, therefore, probably be found possible to record even demi-semi-quavers by this method. An attempt to record a rather fast piece of music is shown in Fig. 3.

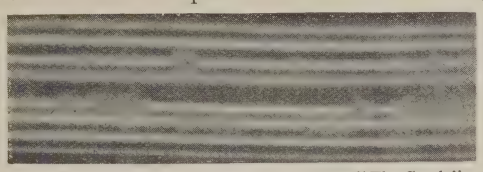

FIG. 3.—Photographic record of a passage from "The Gondoliers" (Gilbert and Sullivan) using eight resonators.

I have, so far, constructed efficient resonators of this kind extending over four octaves. It is obvious that if the method can be made to cover the whole range of musical sounds, a very rapid and convenient method of sound analysis will be at our disposal.

Mendelism and Evolution.

As a member of the British Association who had the privilege, by the generous hospitality of Mr. Richard Marsh, of seeing the white and brown Indians from Panama at Mr. Marsh's temporary residence near Prescott, Ontario, I should like to comment briefly on Mr. Julian Huxley's letter on the subject in NATURE of September 27. It seems to me that there is some degree of inconsistency in Mr. Huxley's remarks. He states that all authorities are agreed that the condition of the white Indians has no racial significance, and yet finally concludes that the case shows how evolutionary change may originate in single mutations of considerable magnitude. I suppose that the phrase "has no racial significance" means that the difference between white and brown Indians is not in any sense or degree similar to the differences between the various races of mankind. It would follow, therefore, that however interesting and important the white mutation may be, it does *not* show that the evolution of human races has had anything to do with mutations of this kind.

It is true that blue eyes are found to be a simple recessive, and many human abnormalities are

known which behave as single Mendelian characters. The distinguishing peculiarity of the white Panama Indians is chiefly, but apparently not entirely, a pigment character. But I believe that there is no human race whose pigment character behaves in crosses with other races as a simple Mendelian recessive; and I believe there is no human race which is distinguished from other races by pigmentation alone. Prof. Karl Pearson has maintained that the white European originated as an albino from a dark race. But it seems proved that the white character of the European does not segregate completely in crosses with other races, and therefore does not behave as albinism. Mr. Huxley states that the white Indians mate almost wholly with other whites. There is a certain amount of separation, but the white girl among the group which Mr. Marsh has with him is the daughter of parents who are both normal brown individuals, and who are both with her. Each of these parents had one white parent.

I hope to give further study to the matter, but so far it seems to me that this case tends to demonstrate the difference rather than the similarity between mutation and evolution. J. T. CUNNINGHAM.

October 1.

The Indian Institute of Science, Bangalore.

IT is a matter of sincere pleasure to those who are students of science in India to read in NATURE of August 2 an account by Dr. Morris W. Travers of the early working and the history of the Indian Institute of Science.

All those who have seen this splendid Institute have a word of praise and admiration for Dr. Travers, who equipped it so that it continues to be one of the finest laboratories in the British Empire. The libraries attached to this Institute are second to none in the world.

That these laboratories will turn out scientific work of the highest importance is only a question of time. With increasing consciousness of the importance of research in India, and the enlarged reforms which give Indians greater scope for intellectual and political activities, the Institute is sure, in time, to fulfil the hopes which its equipment inspires.

When the political status of India is that of a free Dominion in the British Empire, the British names which will be written in golden letters for bringing about that happy state of affairs will not be those of statesmen only, but will include also prominent chemists such as Crum Brown for giving us Sir P. C. Rây, the founder of a school of chemical research in India, Donnan and Thorpe for inspiring the largest number of physical and organic chemists in India, and above all Travers, for building the Indian Institute of Science at Bangalore. (Director of University Chemical Laboratories, The Panjab University, Lahore; and Hon. University Professor of Chemistry, Benares Hindu University).

Benares, September 9.

Gravity Measurements in Deep Water.

ATTEMPTS at determining the gravity force over the oceans do not seem to have met with unqualified success. The following suggestion, so far as I know, is new. Possibly some objection to its use may exist.

A pendulum of the usual type is suspended within a steel vessel of sufficient strength and lowered on a sounding wire to the bottom of the ocean. The verticality of the steel vessel is secured by suspending it from a tripod which takes up a stable position on the sea-floor.

Vanes attached externally to the steel vessel ke it from taking up a vibratory motion, and a surroun ing screen protects it from possible currents. With the vessel there is a photo-electric cell; a small dr battery and lamp; and a simple electromagnet arrangement for the release of the pendulum, whic while being lowered, is held by this release in deflected position. A recording thermometer is al contained within the vessel. A single insulated wi makes connexion with the ship.

When the pendulum has been for some time the bottom, so as to take up a constant temperatur and to allow for initial settlement, it is released by momentary current from the ship. It now falls int vibration, and at each vibration screens the phot electric cell from the lamp. The periodically inte rupted current so created reaches the ship throug the connecting wire.

It is desirable to compare these vibrations wit the vibrations of a standard pendulum upon th land. This is accomplished by means of wireles The current from the submerged apparatus, afte reinforcement, operates the wireless of the ship, an so is transmitted to a station on the land. O alternatively, the vibrations of a shore pendulu are transmitted to the ship and the comparis carried out on board. J. JOLY.

The Institute of Catalan Studies at Barcelona.

IN June last, Prof. Dwelshauvers, the Belgia philosopher, was dismissed by the Spanish Directorat from his position of director of the Laboratory o Experimental Psychology at Barcelona. The reason given for his dismissal were that his researches wer frivolous, and that as the results were only publishe in a foreign periodical, *L'Année psychologique*, th work must stop on grounds of economy.

The Laboratory was under the patronage of th Institute of Catalan Studies, against which a genera attack has been made by the Spanish Government o the ground that its tendency is separatist and sub versive. Public opinion in Barcelona hotly resented the action against Prof. Dwelshauvers, and one hundred and twenty-five professors and science teachers signed a letter of sympathy and protest, which was published in the daily press.

The Directorate professed to consider this letter an insult to the military government, and it was announced that unless an apology was publicly made by the signatories they would be dismissed from their posts. The professors replied that their action was dictated by sympathy with a colleague and had no political significance, and that therefore they had nothing to withdraw. In consequence they have all been dismissed.

Only those who know the work of the Institute of Catalan Studies can appreciate the result of this: practically all the higher education of the Catalan provinces has ceased, for, with the exception of the Castillian University in Barcelona, the whole higher and technical education was in the hands of the Institute.

Among those dismissed are several with reputations outside Spain, including S. Pi i Suñer, Director of the Advanced School of Agriculture; S. Campallans of Louvain and Charlottenburg; Prof. Pau Vila of Geneva and Grenoble; and Prof. Pompeu Fabra, the well-known philologist and the virtual creator of modern literary Catalan.

JOHN LANGDON-DAVIES.

Geology and Evolution.[1]

By Prof. W. W. WATTS, F.R.S.

WHILE astronomy has given us the conception of illimitable space, it has done much to d troy what has been called the anthropomorphic v w of creation. Geology, on the other hand, has owed us with an almost limitless conception of me, but has done something to rehabilitate the im- p tance of man as the highest product yet reached in t long history of the earth.

This it has done, in the main, through the intense r lity that it has given to the conception of evolution. Although several authors, and two in particular, have pointed out that such a conception could not have been f med without the postulates of time and continuity oexistence contributed by geology, it is scarcely real- ed how much geological labour on the life of the earth, ad on life on the earth, as summed up by Lyell and ouped and presented by him in his great work on "The Principles of Geology," was necessary to give to olution a concrete and cogent application. The f ction of this labour could scarcely be better indicated tan by the position of geology as displayed in Lyell's rlier editions. The modern reader of them is con- tually haunted by the feeling that the author was f ling and struggling for a single missing generalisation vich he failed to find; and although, in almost every anch of the subject treated, Lyell leads up again and ain to the missing conception, and though the facts ad inferences which he marshalled can now be seen t be marching on this great idea, he never quite sceeded in attaining it for himself. It was left for lurwin, than whom no one was more conscious of what l owed to Lyell, to see that the facts must rest on sme great single fundamental principle, to realise that is principle was evolution, and to apply it to his own anch, the development of life.

Lyell had proved that the long history of the earth recorded in the rocks revealed the operation of uses, small in relation to the earth as a whole, but rsistent, the majority of them still in action. It was further debt to Lyell that Darwin should bring in e continuous operation of small causes as the achinery operating and guiding the evolution of life.

Though the work of geologists, as summed up in yell, provided the starting-point for the conception of ganic evolution, it did not stop here. The idea of niformitarianism in which that work culminated was eant as a reaction against the fantastic operations stulated by the Catastrophists, and was never tended to imply that these causes in the past were ways balanced or distributed as they now are. There as in Lyell's statements nothing to indicate that enudation or earth-movement might not have been ore active at periods of the past, that organic change ight not accelerate or slow down, that there might ot be variations in the trends of continental or eanic development resulting in climatal and other anges, or that the very sources and intensities of nergy from outside or inside the earth might not eriously vary. Only, warrant must be found for all such suppositions with regard to the earth of the past from fuller study of the earth of the present. If we recognise the inner spirit which inspired the eloquent words of Lyell, when he had grasped that Darwin had supplied the one missing idea, we cannot fail to see that his Uniformitarianism included evolution as one of the "existing causes" to be taken into consideration.

The physiology of the earth, however, is that of a very complex organism, and we are sure that we do not yet know all the forces internal and external acting upon it, still less their relative value and intensity, their distribution and variation in the past, or the precise records which each is capable of imprinting on the rocks of the earth-crust. It is becoming clearer that there has been a periodicity in the stages of development of the earth-crust, and that on these great pulses of earth-life there have been imposed innumerable waves of smaller cycles; and that, on account of their interference with, or reinforcement of, one another, the simpler type of cyclic repetition which might have been looked for in the history is masked and broken and diversified by actual happenings of an infinite variety. Van Hise more than once complained of the tendency of geologists to adhere to single explanations of events, and advocated the necessity of considering the co-operation of many causes; and it may well be that in many outstanding problems such as past glacial or tropical periods, coral reefs, stages of earth movement, progression and regression of the oceans, we may find the ultimate explanation in the interaction of a number of "true causes."

During the long period of time comprised in the history from the Cambrian Period onwards, the slow and persistent evolution of plant and animal life went forward and left ample record in the rocks. To warrant a belief in organic evolution, we are no longer solely dependent on reasoning founded on existing organisms or on the facts of their ontogeny and distribution. As M. Marcellin Boule says in his work on fossil man, ". . . pour tout ce qui a trait à l'évolution des êtres organisés en général, le dernier mot doit rester à la Paléontologie quand cette science est en mesure de parler clairement. Les plus fins travaux anatomiques, les comparaisons les plus approfondies, les raisonnements les plus ingénieux sur la morphologie des êtres actuels ne sauraient avoir la valeur démonstrative des documents tirés de la roche où ils sont enfouis et disposés dans leur ordre chronologique même."[2] Although we are only too painfully aware of the innumerable chances that conspire to prevent an animal or plant from securing immortality by preservation as a fossil, the finding of better-preserved material, the more skilful preparation of it for examination, and the application to it of refined biological methods, such as careful dissection and the serial sections of Prof. Sollas, are giving us more complete and accurate knowledge than ever before. It may now be confidently stated that many of the most crucial links in the chain of evolving life are in our hands, that they actually lived in the past, and that their fossil forms show their

[2] Marcellin Boule, "Les Hommes fossiles," p. 453

relationship to their predecessors and successors. The time has come when Darwin's famous chapter on the "Imperfection of the Geological Record," an apology written with the most balanced criticism and unbiassed judgment, should be re-written and revised.

It is true that we seem as far as ever from unveiling the points of divergence of the great phyla, and we can but feel that the time from the beginning of the Cambrian Period onward is but a small part of the whole history of life on the earth. As with antiquarian research, each new discovery in geology, whether on the physical or the biological side, only brings these distant ages more fully into view and emphasises their modernity and their likeness to our own time. Hutton's famous dictum that he saw "no vestige of a beginning, no prospect of an end," is to-day more true than ever, when we regard the evidence of stratified rocks. But we know enough to convince us that within post-Cambrian time evolution has steadily proceeded from general to special, from simple to complex, from lower to higher efficiency.

In almost every subdivision of the animal kingdom, and in not a few branches of the vegetable kingdom, lines of descent and directions of specialisation have been made out, sometimes visibly operating throughout whole systems, but more usually through smaller divisions of the record; and this in the former kingdom not only among vertebrates but also among the invertebrates and even their lower sub-kingdoms. It may even be stated that in methods of defence, in food procuring, in the attainment of favourable positions and attitudes, something very closely imitating what would be expected on the doctrine of the origin of species by "survival of the fittest" has again and again occurred.

The essence of evolution is unbroken sequence, and when we consider the extraordinary delicacy of the adjustment of life to its physical and organic environment, the mutual interdependence of life forms, and the necessity to them of such factors as favourable range of temperature, food, climatic conditions, soil, and the continuity of the "element" in or on which they live, it is most wonderful that in the vast lapse of post-Archæan time it has been possible for life to exist continuously, and continually to evolve, throughout those long ages. And this in spite of the fact that, although the main chain has been unbroken, conditions have, in many cases, been so unfavourable that whole groups have flourished and died out, while others have become so attenuated that only a few survivors have been left, highly restricted in distribution, to burgeon out again when the unfavourable conditions were removed, or in other places where conditions have again become more favourable to them.

That life has survived continuously in spite of the vicissitudes through which it has been compelled to pass, and the frequent convergence upon it of unfavourable conditions, may well be taken to heart by those who fear that civilisation will be brought to an end by the misuse of the powers that itself has evolved. They may surely take courage and trust that the remedy for these evils will come, as it has in innumerable other cases, not from conventions and understandings that, as all history shows, will be mere scraps of paper, but from the intensive application to them of the very science which has evolved them.

Although the geological record is and possibly will always remain incomplete, it has yet proved remarkably representative, and certain outstanding facts have been made out which are sufficient to show that the lines of organic evolution as recorded in geology are in accordance with what is theoretically probable, and with those taken by the evolution of domesticated organisms and by human arts and inventions.

(1) There can be no doubt that the stages of organic evolution are correlated with, and were actuated by, the stages in the inorganic evolution of the earth itself; that climatic change was effective in inducing migration, and thus in sharpening the struggle for existence against both enemy organisms and changed physical environment; that extension and restriction of land and water areas in some cases brought about keener and more varied competition, change of habit or food, and in others the destruction of potential enemies and the securing of the advantages of a fair field for the survivors; and that activity of the earth-crust in such things as deposition and mountain building provided conditions for the existence of an increased range of varieties and the consequent struggle between them. If we are not allowed to say that this brought about the survival of the fit, it at least caused the destruction of the unfit.

(2) It may be stated as a biological law that every locality becomes "full" of life, forms arriving or evolving to take advantage of the special facilities offered. In consequence, resistance to the incursion of new forms, even if they are exceptionally equipped, is very great, and it is only occasionally that such new forms can make good their immigration. There are, of course, marked exceptions, but these generally occur when degeneration or overgrowth in size accompanied by neglect of means of defence has occurred, or when an area has been for so long sheltered from the wider and more general course of evolution that it has fallen seriously behindhand in the race.

The geological record gives indirect evidence of the same "filling" of areas in the past in the extraordinary slowness with which advanced types, that have eventually made great headway, established themselves after their introduction; the earliest fishes, reptiles, and mammals are cases in point. Imperfect as the first members of these groups undoubtedly were, they must, even shortly after their introduction, have possessed considerable advantages over the older and established forms with which they found themselves in competition. In size and strength they were doubtless inferior, and probably they must have taken long periods to make good their advantage. But in all such cases the new forms went for a long period into "retreat," and in face of the apparent slowness of their evolution and the bitter competition to which they were subjected, it is remarkable that they overpassed the troubles of racial youth, and eventually took the place to which they were entitled in the scheme of life. It seems justifiable to believe that there must have been at least some well-equipped types which did not survive competition in these early stages, but went under with all their promise of future success. We can easily imagine that the survival of such, had it

curred, may have altered the whole course of evolution and produced a life story very different from that we know to-day, and of which we ourselves form no small part.

(3) Not less remarkable than the period of "retreat" is that of booming development which at last came to each successful modification. In this connexion we can instance the *pleine évolution* of the graptolites, the echinoids, ammonoids, and belemnoids, the fishes, reptiles, birds, and mammals, each in its own time. Each slowly but surely built up its supremacy, and then intoned through long ages as the lord of creation in its own element and in its own day. Both the period of sanctuary and the subsequent boom can be closely paralleled by the case of many human inventions and in the occupations and history of mankind.

(4) While there are outstanding cases in which a line of advance is taken that is capable of successive improvements and leads on to continuous success, there are many others in which the line of advance, though temporarily advantageous, has only been carried through a limited number of stages. Eventually it has failed either by its inherent inadequacy or by imposing too heavy a burden on the economy of the organism that it was unable to bear the cost.

The only example I need quote, though there are many others, is the use of defensive armour, spines, plates, hooks, horns, etc. These provide an obvious method of resistance to attack, and this defensive attitude has been practised by one group of organisms after another, but always with the same disastrous result, the imposition of a fatal strain on the organism to meet renewed, perfected, and more vigorous attack. The spinose graptolites and trilobites, the armoured fishes and reptiles, are cases in point, and in the last of these examples, at least, victory rested with the acquirement of swiftness in movement, accompanied by increasing power of attack such as is given by the development of teeth or claws or both. Again and again in the Tertiary era one group of mammals after another, before, or more usually after, the attainment of great size, has taken to some means of sedentary defence, and in every case the cost of upkeep has been too great and the group has gone under. Every time the race has been to the swift, active, and strong, and those that trusted in "passive resistance," in "defence and not defiance," have gone under in competition with those that have been prepared to face the risks involved in attack. The fact that turtles and armadilloes have survived to the present endorses rather than vitiates the principle.

Other cases of rapid decline or sudden disappearance are more difficult to account for. The waning of the brachiopods but yet not their disappearance, the disappearance of the pteridosperms, the rugose corals, the belemnoids and ammonoids synchronising with the vanishing of many orders of reptiles, will long furnish subjects for research by biologists and geologists. It may well be that the explanation will often lie along biological rather than physical lines, such as those suggested for the graptolites; Lapworth pointed out that their disappearance—in spite of a brave effort of passive resistance—synchronised with the great development of fishes, and the assumption by them of many of the functions previously discharged by the trilobites. In other cases the explanation may be more in the direction of that given for the reptiles to be referred to later.

The rarity in the geological record of some of the stages in evolution, and the absence of others which must surely have existed, may receive some explanation from what has frequently occurred in the history of human invention. If variants arise and are subjected to intense competition, they have no chance in the struggle for existence unless they show rapid improvement and development of the favourable variations within a few generations. Hence the numbers exhibiting each of the early stages of change will always be few and the chances of their preservation slight. Those who have tried to work out the stages in the history of an invention, for example, will appreciate the rarity of "missing links" and the difficulty of filling in every step towards the later perfection. These are looked upon as "freaks" and, unless they present real and marked improvement, are never manufactured on a large scale. Their numbers consequently are few, and many of them are the victims of experiment and often do not survive the experience.

(5) Perhaps the most wonderful result disclosed by a study of the later part of the geological record is the steady and unbroken evolution of brain from the earliest vertebrate animals to the present. The exceeding slowness of the process in its early stages is not less wonderful than its acceleration during the latest stages of geological history. The disappearance of so many orders of reptiles at the end of the Mesozoic Period, at the close of a long and most promising chain of evolution, indicates that there was some inherent weakness underlying the line of evolution entered upon by them, which proceeded so far and favourably that it was impossible to retrace the path. This may well have been connected with the substance or construction of brain and nerve. If so, this side of evolution has to be seriously reckoned with, and it may be that the fundamental weakness of physical as opposed to intellectual evolution brought this flourishing and well-developed group to its end.

It has, of course, been suggested by Starkie Gardiner and others that the destruction of Mesozoic life types was brought about by physical changes; but, apart from the fact that the particular changes supposed by the former did not as a matter of fact occur, the entire explanation provides a cause utterly insufficient in comparison with the potency of organic struggle against creatures better endowed with warm blood, adequate brain substance, and the activity and enterprise springing therefrom.

In spite of the evidence of acceleration as the higher ranks of animals are reached, and in spite of the extraordinary efficiency of the human brain and all the benefits to the organism it brings about, we may well be appalled by the æons which have been used up and the millions of varieties which have passed away in the production of this, the most efficient scientific apparatus yet invented or evolved.

(6) If, however, it has taken long ages to evolve an animal capable of a broader geographical distribution than any other, with a constitution capable of withstanding the widest ranges of heat and cold, and of peopling the world from its tropical deserts to its polar

wastes; and to endow him with a brain by virtue of which he has made himself master of the earth and all its living inhabitants; it has taken no less time for the evolution of the many factors without which his present success would have been impossible. To pick out a single instance, probably few things in the whole story of life have been more fruitful in effect than the appearance of the grasses in late Eocene times, followed by their rapid evolution and spread in the Oligocene and under the direction of the critical events of the Miocene Period. Starkie Gardiner in an admirable paper first directed attention to the vital importance to the animal evolution of the world in general, and to the welfare of man in particular, of this step forward. It was followed by great changes in the insect world, by the rapid production of herbivorous mammals endowed with speed, great migratory powers, special dental and other anatomical adjustment to the new foods, and the institution in their herds of a discipline, subordination, and leadership which are almost tribal. These last qualities were rendered doubly necessary by the consequent rapid development of carnivora, and the need for "scrapping" passive and even active means of defence in order to secure the power, speed, and reserve necessary to follow their food harvests over great stretches of country. At the same time the habits and instincts thus brought about were those which man, by domestication, has been able to turn to his own ends. Thus at a blow, as the outcome of this stage of Tertiary evolution, there became available for mankind not only his chief plant food and drink, his luxuries as well as his necessaries, but also his chief animal foods, together with his aid from the speed, strength, service, and endurance of the animals which he domesticated, and to which he assumed the position of leader to the herd.

While with the aid just described it was possible for mankind to progress far on the road of civilisation, progress would have been stopped, and as a matter of fact was seriously retarded, until the discovery and utilisation of the solar energy stored up in the earth's crust during the Carboniferous and subsequent periods in the form of coal and other fossil fuels. The very exceptional conditions, climatal, geographical, and botanical, requisite for coal formation, occurred all too seldom in geological history, but it has so happened that few areas of the earth are devoid of coal belonging to one period or another; and the shaping of kingdoms and dominions has been such as to include supplies of fuel in most of them. Whatever may be the main sources of energy in the future, radiant, intratelluric, hydraulic, tidal, atomic, we have been largely dependent in the past, and probably shall continue to depend for many years to come, on that portion of the solar energy stored up by vegetation, and especially on that preserved in the earth-crust in the form of coal.

Again civilisation must have been greatly hampered or driven into a different course but for the agencies which have sorted out from the medley of materials of which the earth is composed, simple compounds or aggregates of compounds, or in rarer cases simple elements, in such a form that they are available for human use without the expenditure on them of excessive quantities of energy. The concentration of metalliferous ores, salines, and the host of other mineral resources has made perhaps the most important contribution of all to the latest stage—in good and evil—attained by civilisation.

Finally, doubt may be expressed whether man could have attained his present position if he had not made his appearance comparatively soon after a period of intense earth activity, when broad areas of newly raised sediment were available for occupation, when the agents of denudation and renewal were in active operation, and when a wave of rapid organic evolution was active. A conjecture may also be permitted that human evolution itself was probably hastened by the latest climatal severity through which the earth passed, the effects of which are only slowly passing away.

Much of what has just been said may revive recollection of an old Swiss guide-book which praised the beneficence of Providence in directing the dreaded avalanches "into the desolate and uninhabited valley of the Trumleten Thal and in sheltering from them the beautiful, fertile, and inhabited valley of Lauterbrunnen." However, it is far from my intention to imply that "everything is for the best in this best of all possible worlds," but only to point out, in reviewing the long chain of events of which we see the present end-product in civilised man, that within the ken of the geologist there have been many critical stages in the earth's history when any marked change in the conditions which then prevailed must inevitably have reacted profoundly upon the development of the human race when at long last it stepped out from the lower ranks to take the earth as its rightful possession.

In the course of the development of both the economic and the scientific sides of geology, the principles discovered and elaborated have fertilised and enriched human thought as expressed not only in other sciences but also in the sphere of literature. As it has become more precise and is able to give a more accurate and detailed picture of the stages through which the earth passed during the long story unfolded by the study of the stratified rocks, it has shown that the earth, though only a minute fraction of the visible universe, has had a wonderful and individual history of its own. The keynote of this history is evolution, the dream of philosophers from the earliest times, now passed from the realm of hypothesis into that of established theory.

We are able to watch the evolution of the oceans and continents, of the distribution of landscape and climates, and of the long succession of living beings on the earth, throughout many millions of years. During these ages we see the action of the same chemical and physical laws as are now in operation, modified perhaps in scale or scope, producing geographical and biological results comparable with those of to-day. Hutton and Lyell discovered for us in the present a key to unlock the secrets of the past; the history thus revealed illuminates and explains many of the phenomena of the present. The outcome of it all is to endow man with a simple and worthy conception of the story of creation, and to fill him with reverence for the wondrous scheme which, unrolling through the ages, without haste, without rest, has prepared the world for man's dominion and made him fit and able to occupy it.

Liquid Air in Mine Rescue Apparatus.

THE Mines Rescue Apparatus Research Committee which was appointed by the Advisory Council for Scientific and Industrial Research to inquire into the types of breathing apparatus used in coal mines, and to determine experimentally the advantages, limitations, and defects of the several types, has recently presented its third and final Report.[1] In the first report, attention was directed to certain serious defects in rescue apparatus, and to the training of rescue brigades; and the lines along which improvement in design was necessary were indicated. In the second report, methods of testing compressed oxygen apparatus were proposed and descriptions of new and improved appliances were given. The third report deals principally with the use of liquid air and liquid oxygen in mine rescue apparatus, and will prove of great interest not only to mining engineers but also to all who have occasion to use liquid air and oxygen.

The report includes, in addition to a detailed description of the new Brown-Mills aerophor rescue apparatus, an exhaustive treatment of the problem of the construction of vacuum storage vessels or containers for liquid air.

Liquid air was first used for mine rescue work in an apparatus known as "Aerolith," designed by an Austrian engineer, Herr Lüss, in 1906. This apparatus, which was not provided with a purifier or regenerator for absorbing the carbon dioxide in the exhaled air, failed to supply an adequate amount of air to the wearer when a heavy task was being performed, and consequently its use was strictly limited. In 1910 Col. Blackett invented a regenerative liquid-air apparatus bearing the name of "aerophor"; but it is this type of appliance in a modified and much improved form that has been installed recently in the Northumberland and Durham rescue stations.

The mode of action of the Brown-Mills aerophor, which is the most efficient and trustworthy of this type, will readily be understood by reference to Fig. 1, which is reproduced from the Report. It consists essentially of a "pack" P or liquid-air container, a regenerator or purifier Q, a breathing-bag M, and the necessary metallic and flexible tubes for conveying the gas from the "pack" to the bag and mouthpiece, and the exhaled air from the mouthpiece to the purifier. Liquid air is poured into the pack through a single central opening, and is absorbed by the calcined asbestos wool WW which is packed tightly in a perforated nickel silver case. The air space C which surrounds this case serves to distribute the liquid during the process of charging, and to collect the evaporated air. The latter passes through a pipe G into the space E, which is loosely packed with asbestos. From the upper side of E the gas flows into a metal warming-pipe H, and thence through the tubular spar A to the breathing-bag. During inhalation, air is drawn both from the bag and the purifier through the valve V_1. The exhaled air passes through the valve V_2 to the purifier Q, where the carbon dioxide is removed by caustic soda, and thence through valves V_3 and V_1 back to the mouthpiece. The space E, in addition to serving as an outlet for the evaporated air, impedes and to a limited degree regulates the flow of heat into the interior of the pack, and consequently controls the rate of evaporation. Immediately after charging the pack, the volume of cold air circulating in E, owing to the low specific heat of the liquid air, is very considerable, and consequently its insulating effect is a maximum. This results, at this stage, in a reduction in the amount of heat entering the inner chamber of the pack, and in a tendency to effect a diminution in the ebullition of gas, while towards the

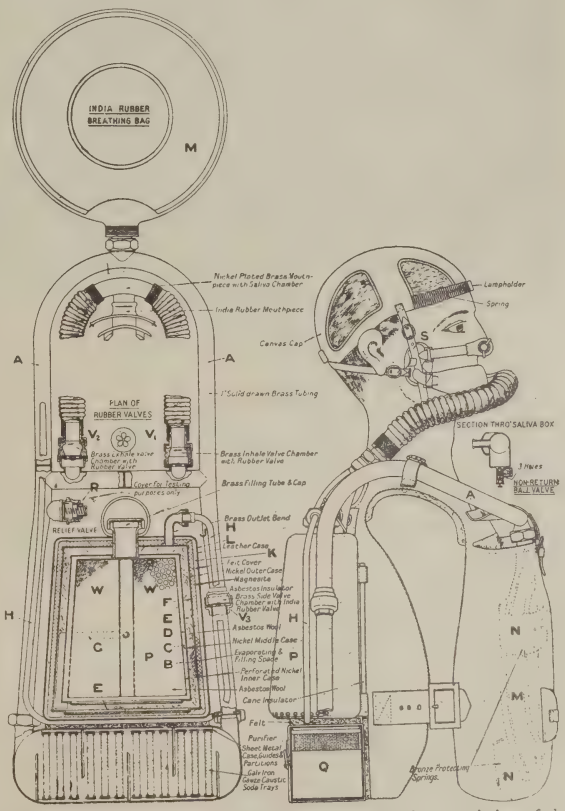

FIG. 1.—Brown and Mills aerophor. Reproduced, by permission of the Controller of H.M. Stationery Office, from the Third and Final Report of the Mine Rescue Apparatus Research Committee.

end of a "run," when the evaporation is flagging, it is stimulated by an increase in the amount of heat across that space. In spite of this automatic means of regulation the discharge is variable, being approximately 30 litres per minute just after charging, and falling off to 8 litres per minute at the end of the two hours' period. An important feature of the appliance is the valve V_3, which prevents the excess of air delivered from the pack during the first part of a run flowing in a reversed direction through the purifier, and thereby rendering the caustic soda comparatively inert by cooling. The pressure of the air in the breathing circuit is controlled by the relief valve R, which is set to operate at a pressure of about 18 lb. per square foot. The total weight of the apparatus, including the approved charge of $5\frac{1}{2}$ lb. of liquid air and 2 lb. of absorbent, is about 40 lb.

[1] Department of Scientific and Industrial Research: Advisory Council. Third and Final Report of the Mine Rescue Apparatus Research Committee. Pp. 32+32. (London: H.M. Stationery Office, 1924.) 1s. net.

The chief advantage claimed for the aerophor, and one that is recognised by the Research Committee, is its great simplicity in use. Compressed air appliances necessitate frequent adjustments, and occasional readings are required to be taken of the pressure-gauge. These are not necessary with the aerophor type of apparatus, and in consequence the wearer is free to devote the whole of his attention to the work in hand. Another obvious advantage is the continuous reduction in the load to be carried when in use, due to the ebullition of the charge.

FIG. 2.—Steel cradles for the transport of containers. Reproduced, by permission of the Controller of H.M. Stationery Office, from the Third and Final Report of the Mine Rescue Apparatus Research Committee.

All existing forms of liquid-air apparatus, with the exception of that designed by Mr. G. A. Griffiths, have one defect in common, namely, the evaporation of the liquid air when the apparatus is not being used. The chief obstacles, however, that militate against the general adoption of liquid air for mine rescue work are connected not so much with the apparatus as with the manufacture, storage, and transport of the liquid. As pointed out in the Report, the manufacturing plant, which is costly, requires skilled attention, and has to be run at intervals to make good the loss by evaporation in the reserve of liquid kept in storage flasks. These flasks, although giving little trouble during normal use at the rescue stations, are so delicately constructed that they require very careful handling when being transported at the surface or underground.

The movements of the flasks during a rail or road journey must of necessity increase the rate of evaporation of the liquid air. Experiments, including those which have been carried out under the auspices of the Research Committee by Dr. Briggs and Mr. G. L. Brown, show that under ordinary conditions the loss by evaporation during transport is nearly twice the loss that occurs when the flasks are stationary. With the view of determining the most efficient means of supporting liquid air flasks during transport, two flasks, each containing 50 lb. of air, were carried i heavy motor ambulance for a distance of 7·6 m over good roads. The first contain which was placed on the floor of car, lost 7 oz., whilst the second ves which was provided with trunni carried in spring-mounted bearin lost 14 oz. This unexpected result v due to the violent swinging of the ves on its trunnions by the movement the car, causing rapid ebullition of air and frequent spurting of the liq from the neck. As a result of this t the gimbal method of support has b entirely superseded by the simple st cradle (Fig. 2), a form of stand wh is giving remarkably efficient servi Storage flasks or containers form essential a part of the equipment liquid-air rescue stations that the Mi Rescue Research Committee is perfec justified in devoting considerable sp to them in its final Report.

The liquid air containers (Fig. are similar in every respect to "thermos" flask, except that th are made of brass or copper inste of glass, and that a small quant of specially prepared charcoal is serted in the vacuum space between the inner a outer vessels. Both vessels are constructed of t

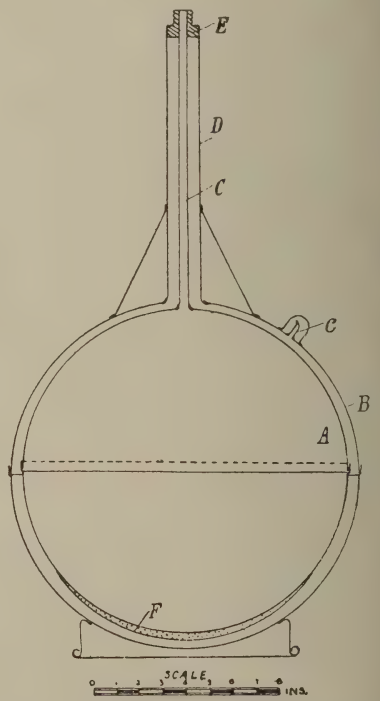

FIG. 3.—German 50-lb. liquid air container. Reproduced, by permiss of the Controller of H.M. Stationery Office, from the Third and Fi Report of the Mine Rescue Apparatus Research Committee.

hemispherical pressings, joined together by a s solder, the two necks C and D being soldered to plug E of solid drawn brass. A conical collar is fix

d the base of the neck for additional support. ir from the vacuum space is extracted through d tube G of about ¼-in. bore. When evacuation plete this lead is pressed flat, and is then burned ith a small Bunsen flame. The lead seal is pro- d by a cup-shaped cap filled with wax or bitumen. surfaces of the globes which face each other across acuum space are very highly polished to reduce ransmission of heat by radiation to the liquid air. e charcoal maintains the vacuum by absorbing as that leaks into the vacuous envelope through orous metals. The remarkable absorptive power harcoal at low temperatures, discovered by Sir s Dewar in 1905, has made possible the use of llic vacuum flasks and is contributing most to rapid expansion that is now taking place in the cation of liquid air and oxygen for industrial scientific purposes. Major Lambert found from periments he carried out for the Oxygen Research mittee that British palm-nut charcoal was capable bstracting the residual air from a vessel, which previously been partially exhausted, to such an nt as to reduce the pressure from 0·0575 mm. to ·00005 mm.

it be assumed that the pressure-reduction factor—ial pressure/final pressure—is directly proportional e amount of adsorbent used, then with the usual ge of 200 gm. of charcoal in a 50 lb. metal ainer, an initial pressure of 0·1 mm. in the vacuum e will be reduced to a final pressure approaching ·00002 mm., at the temperature of liquid air. At exceedingly low pressure the loss of heat by con- ion across the vacuum space is negligible in com- ason with the loss by radiation. For this reason it is not necessary to reduce the pressure in the envelope of a Dewar metal flask to the very low value required with the glass flask in the preliminary operation of pumping.

In order to determine the decay of the vacua of Dewar metal flasks, Dr. Briggs, a member of the Research Committee, has conducted a series of valuable experiments on 3-litre flasks. The apparatus used enabled the outer wall of a vessel to be punctured, the pressure inside the envelope to be measured, and the puncture sealed without damaging the flask or destroying the vacuum. These experiments showed the average rate of decay of the vacuum to be about 0·011 mm. per month. This slight, though continuous, deterioration of the vacuum, due to leakage of air through the excessively minute pores of the metal, necessitates periodical re-evacuation of the envelope, an operation which is performed at certain English rescue stations by the simple hand-driven Geryk pump.

Very interesting particulars concerning the cost of making liquid air have been supplied to the Research Committee by the chief English liquid-air stations. At Station A the 10-years-old plant was run for 477 hours, during which time 8705 lb. of liquid air was produced with a power consumption of 0·78 k.w.h. per lb. The cost, including power, repairs, chemicals, oil and water, but not including depreciation, establishment charges and labour, was 14·6*d.* per lb. At Station B, 8837 lb. was made in 440 hours with a power consumption of 1·17 k.w.h. per lb. The cost, including power, repairs, chemicals, oil and water, was 2·7*d.* per lb. Depreciation on the plant at 10 per cent. per year amounted to 4·3*d.*, and establishment charges to 4·2*d.* per lb., giving a total cost of 11·2*d.* per lb.

Obituary.

Dr. S. H. C. Martin, F.R.S.

SIDNEY MARTIN, the second son of the late John Ewers Martin, was born in Jamaica in 1860, and entered University College, London, in 1876, where he was a fellow-student and contemporary with Victor Horsley, Halliburton, and Frederick Mott. At this time many medical students at University College had a sure foundation for their subsequent medical studies by following an extended course of instruction in biology, chemistry and physics, and Martin was one of these. He took his degree in science at the University of London in 1878, being especially attracted to biology, largely owing to the stimulating influence of that inspiring teacher, Sir E. Ray Lankester. Afterwards, during his medical studies, he came under the influence of the late Sir John Burdon Sanderson, then Jodrell professor of physiology, who was not only a physiologist but also an experimental pathologist.

After graduating in medicine in 1883, Martin began working, at the instigation of Burdon Sanderson, as an investigator in the Jodrell Laboratory, then under the control of Prof. Schäfer, who had succeeded Sanderson on the latter's appointment to the chair of physiology at Oxford. This period of the early eighties was one of great activity in physiology and pathology in Great Britain, and Martin devoted himself to what was then a new field, namely, the investigation of the chemical side of vital processes, and more especially to an inquiry into the nature of the so-called toxic proteids. At this time the number of workers in this branch of knowledge was extremely limited, especially in Great Britain, and Martin carried out a series of researches not only on abrine and ricine but also during a number of years on the wider question of the nature and mode of action of the toxic substances elaborated by the activity of micro-organisms in infective diseases, more especially diphtheria, tetanus and enteric fever. He developed this subject in a long series of investigations recorded in his Goulstonian and Croonian lectures delivered before the College of Physicians in 1892 and 1898.

Although Martin's main work as an investigator was in the domain of chemical pathology, and he was one of the earliest workers in Great Britain on this subject, he was a recognised authority on pathology and pathological questions in the widest meaning of the terms. Thus he had an accurate and extensive knowledge of gross morbid anatomy and was professor of pathology at University College from 1895 to 1907 and the author of a text-book on pathology. Further, all his work, both as an investigator and as a teacher of pathology, was directed to the furtherance of clinical medicine and towards increasing the power of the physician to cope with disease, and Martin was a practising physician throughout his career. He was a teacher at University College and Hospital throughout

his life, from his appointment as assistant physician in 1891, to the time of his very sudden death whilst in active work. In addition to the posts he held in his old school, he had occupied numerous other appointments, as curator of the museum and pathologist to the Middlesex Hospital, pathologist and assistant physician to the City of London Hospital for Diseases of the Chest, and physician to the Hospital for Consumption, Brompton.

In 1895 Martin was elected F.R.S. and he served on the council in 1919–1921. He was elected F.R.C.P. in 1891, served on the council 1909 to 1911, was censor in 1915-1916, and gave the Lumleian lectures in 1915. He did a considerable amount of public work and was a member of the Royal Commission on Tuberculosis, in the work of which he took an active part. During the War he served on the staff of the 3rd London General Hospital, and was a member of the Committee of Reference that carried out important work in connexion with the provision of medical officers for service overseas. He was also a member of the Executive Committee of the Imperial Cancer Research Fund from its inception in 1902, and had recently been appointed chairman in succession to Sir William Church.

MR. F. H. BRADLEY, O.M.

IN Francis Herbert Bradley, who died on September 18 in a nursing home after a short illness, mainly the result of an accident, British philosophy has lost its most distinguished representative. Born in 1846, his life covered a period of unexampled activity in this department of thought, of which his may be said to have been the central influence. Himself profoundly influenced by Kant and Hegel, and having the advantage of the stimulus which the earlier expounders of their philosophy, notably Caird and Green, gave, his method and his achievements were entirely his own, and he stands out as one of the great line of Locke and Berkeley and Hume.

It is difficult in an obituary notice to indicate the ground of this claim. We have heard of a poets' poet. Bradley was a thinkers' thinker. He never lectured and was under no temptation to popularise his thought. On one occasion of controversy with a distinguished opponent, he complained of him that he lectured instead of writing philosophy. What gave Bradley a unique position among his contemporaries was, in the first place, the vigour and incisiveness with which he put an end to old ideas, and in the second place, the splendid lucidity of the statement, and the thoroughness in the detailed application of the ideas which he believed had to be put in their place.

It was thus in his "Ethical Studies," "the most readable work on serious philosophy in English," as it has been called, which appeared in 1876, that Bradley gave the *coup de grâce* to Hedonism, and in the celebrated chapter on "My Station and its Duties" provided the concrete foundation on which the best ethical thought of our time has since been content to build. Unfortunately, this book has long been out of print. Bradley had the intention at one time of reprinting it with notes and additions, as has recently been done with the "Principles of Logic," and it is greatly to be hoped that it will be found he had carried out part of this intention.

The "Logic," which appeared in 1883, occupies a similar place. On one hand, the theory which, as in Bain and Mill, attempted to found inference on the as ciation of ideas, is subjected to annihilating criticis on the other hand, for the old idea of the syllogism linear inference from isolated elements of identity, v substituted the idea of continuity with the orga system of experience as the principle of the forw movement of thought. The fertility of Bradley's w in these fields is familiar to students of philosophy the brilliancy with which the underlying ideas of " Principles of Logic " have been applied in logic Bosanquet, and in psychology by Prof. G. F. Stout.

It is, however, in his last great work on "Appearar and Reality" (1893) that Bradley's originality is m conspicuous. As in the previous books he had wag relentless war against abstract ideas in logic and ethi so here in metaphysics—or the search for ultim reality. The goal here is not to be found in any of t forms (space-time, quality, soul or self) in which phi sophers have sought it. Even the worlds of thoug and will give us only partial aspects of the compl experience which alone can satisfy. Taken in the selves they are the products of abstraction—*res ration* as Spinoza would have said. The ultimate reality something at once simpler and more complex. It simpler because it is something present with us all simple or again in exalted feeling; it is more compl because it must be conceived of as containing all t subtleties of difference and relation that science a philosophy find in it.

The dialectical form of this work, the deadly thru with which the claim of each category is transfixed, h given the impression, even to philosophers, that it mainly destructive. It has been called the *dis*appea ance of reality. What Bradley, on the contrary, w asserting was the growing fulness of the world in whi we live as we rise from the more abstract and mo obviously inadequate and relative forms of reality, su as space-time or matter, to the more concrete of huma personality and its life in art, morality, and religio Bradley was a relativist before Einstein. But h relativism differed from Einstein's in being univers and in being balanced and outweighed by his sense the necessity of presupposing an absolute as at once th criterion of the degree of relativity of any particular for of reality and the source of its significance and value.

Taken along with the volume of collected articl "Essays on Truth and Reality" (1914), and the not and "Terminal Essays" in the new edition of th "Principles of Logic" (1922), the essential constructiv ness of Bradley's work is unmistakable. But it is not b his contribution to idealistic philosophy alone that h influence on his generation has to be measured. It wa the clearness and uncompromisingness with which th main principle of idealism was stated in his chief work that, more than any other single influence, was th source of the violent reaction against it which marke the end of last century and the beginning of this unde the forms of pragmatism and the new realism. Th battle is still hot, and this is not the place to enter int the issues that are there being fought out. When on of the contributors to the recent volume on "Con temporary British Philosophy" suggested that i should be dedicated to F. H. Bradley as a tribute t "the chief," among the representatives of ever school, there was no dissentient voice except Bradley' own to forbid it.

J. H. MUIRHEAD.

MR. H. G. SMITH.

By the death on September 19, at Roseville, Sydney, New South Wales, of Mr. Henry George Smith, Australia loses one of her most eminent scientific men. Mr. Smith, who was born at Littlebourne, Kent, seventy-three years ago, was for many years assistant curator and economic chemist at the Sydney Technological Museum, and upon his retirement a few years ago he continued his researches in the Organic Chemistry Department of the University of Sydney. In collaboration with Mr. R. T. Baker, formerly curator of the Sydney Technological Museum, he carried out a series of investigations extending over thirty years which have thrown much light upon the scientific characteristics and economic possibilities of the essential oils and other products of the Australian flora. The main results of this work were published in two volumes entitled "A Research on the Eucalypts and their Essential Oils" and "A Research on the Resins of Australia." Mr. Smith was an unflagging worker, and his original papers, contributed to various scientific periodicals, number well over a hundred. Owing to the bulk of his work having been published exclusively in Australian journals, it received fuller recognition in Australia and America than in Great Britain.

Mr. Smith was an original member of the Australian National Research Council, and at various times he filled the offices of president of the Royal Society of New South Wales, president of the New South Wales branch of the Australian Chemical Institute (1922–23), and president of the chemistry section of the Australasian Association for the Advancement of Science. In the last-named capacity he delivered his presidential address on the chemistry of the Australian flora at Wellington, New Zealand, in 1923. He was an honorary member of many British and American scientific corporations, and was recently awarded the Syme Prize of the University of Melbourne as an appreciation of his services to scientific research in Australia. His character was marked by simplicity and sincerity, and he will be remembered as an outstanding pioneer of Australian chemistry.

WE regret to announce the following deaths:

Mr. J. E. Campbell, F.R.S., fellow and tutor of Hertford College, Oxford, and mathematical lecturer in University College, Oxford, on October 1, aged fifty-two.

Mr. Otto Hehner, president in 1891 of the Society of Public Analysts, on September 9, aged seventy-one.

Mr. J. Q. Rowett, who financed Shackleton's last expedition in the *Quest*, and provided funds for the establishment of the Rowett Institute of Research in Animal Nutrition in connexion with the University of Aberdeen and the North of Scotland College of Agriculture, on October 1, aged forty-nine.

Current Topics and Events.

AN important find of dinosaurian remains of Karroo age has recently been made a few miles west of the north-western shores of Lake Nyasa. The bones, including vertebræ, a scapula, and a coracoid, are on the whole in a good state of preservation, and it is hoped that many others will be found in the course of the more detailed examination of the area to be made in the near future. These are the first remains of the kind to be found in Nyasaland or elsewhere in this part of Africa; they have been identified by Dr. S. H. Haughton, of the Geological Survey of South Africa.

IN our issue of December 29, 1923, p. 925, we published an article commenting on the present system of distributing Government publications and their cost. In the issue of March 15, p. 407, we returned to the question, referring particularly to the question of price, and it was stated that the Library Association had made representations to the Treasury on the subject. As a result, public free libraries supported out of the rates, and the libraries of universities and university colleges in receipt of assistance from the University Grants Committee, were allowed to purchase Government publications at half-price. The matter also came before the Council of the British Association at the Toronto meeting (NATURE, August 9, p. 251). Dissatisfaction with present arrangements was further expressed at the annual conference of the Library Association held at Glasgow last month, when a unanimous resolution was passed instructing the Special Committee of the Association which has dealt with the matter to approach the Treasury again with the view of reducing considerably the present prices of Government publications and of establishing Depository Libraries in selected geographical areas." A Memorandum has therefore been drawn up setting forth the facts as to the costs of Government publications and asking that "the Government should recognise a comparatively small number (about 20) of the largest public libraries in selected geographical areas as 'Depository Libraries' where all Government publications could be freely consulted by the public *immediately* after publication." We hope that the Chancellor of the Exchequer will give the most careful consideration to the suggestions which the Library Association is making, and that some way of meeting the difficulties of the present position will be found.

IN our issue of January 12, p. 52, we published a criticism of the argument put forward in favour of the view that foot-and-mouth disease may be introduced into Great Britain by migratory birds. A similar question is raised by a paper by W. P. Taylor and H. C. Bryant on "Relation of Wild Birds to the Foot and Mouth Disease" (*California Fish and Game*, July 1924), in which the position is reviewed in relation to the conditions in Mercred County, California, mainly with regard to local spread rather than to introduction from a distance. The arguments for and against the bird theory are marshalled, the latter preponderating; but admittedly there is no proof, either positive or negative. We do not think that it has been seriously suggested in Great Britain that even if birds were proved responsible the remedy would lie in measures for their extermination, but here we read, under the heading "Psychological

Aspect," that in California this policy is strongly advocated by interested but ignorant parties. The writers even seem, at first sight, to make some concession to this view by devoting a section to the relative merits of different methods of destruction, not excluding poison gas; but this is perhaps mainly for the purpose of demonstrating the futility of all of them. They point out, for example, that shooting may lead to the wider dispersal of the surviving birds, and that officials charged with measures for the control of birds might become more dangerous potential carriers of infection than the birds themselves; only the killing of turkey buzzards which actually come to feed on diseased carcases is considered feasible. The writers conclude that any policy of destruction would be unjustifiable, impracticable, and useless—or worse. They might have added that any wholesale elimination of bird-life would probably deal an effective deathblow to all agriculture in the region.

THE Carnegie Institution of Washington, acting through its Advisory Committee in Seismology, and the Seismological Society of America, have agreed on certain methods to promote seismological research in both scientific and practical lines. The Advisory Committee was appointed four years ago, and decided to limit its work at first to the west coast region of the United States, where earth-movements occur in considerable variety. It has had the advantage of the co-operation of the Ukiah and Lick Observatories, the U.S. Coast and Geodetic Survey, the U.S. Geological Survey, and the U.S. Hydrographic Office, and can already point to some valuable results. The two observatories mentioned are continuing their observations of latitude in order to establish or disprove the northward crustal drift indicated by earlier observations. A fault-map of California has been published, and also a bathymetric chart of the continental shelf from San Francisco to Point Descanso, and a new primary triangulation has been made of the entire coast region south of San Francisco. The Seismological Society was founded in 1906, and its Bulletin, first published in 1911 and issued quarterly, has produced many useful memoirs. The agreement with the Advisory Committee provides that the latter shall bear the cost of printing specific articles which the Society could not otherwise undertake, and this enables the Society to issue an invitation to students of seismology and related subjects to use the Bulletin as a means of communication with their fellow-workers in other countries. The chairman of the Committee on Publication is Prof. S. D. Townley, Stanford University, California.

THE fifth annual report of the Tidal Institute of the University of Liverpool records an important administrative change: the Institute is now governed by a joint committee of the University and of the Mersey Docks and Harbour Board, one of the University representatives being nominated by the Admiralty. The same committee also governs the Bidston Observatory. The Liverpool Steamship Owners' Association has provided nearly all the fun required for the Institute during the past year a also for the coming year. The Institute is al making preparations for partial self-support by e gaging in commercial work on a comparatively e tensive scale. A special method of analysis and pr diction of tides suitable for large schemes of routi work has been devised; a tide-predicting machine also being constructed for the Institute, the co being defrayed by generous gifts from Liverpool shi owners. The machine, which is to be housed at t Bidston Observatory, is to be much larger than t Kelvin machines, and will incorporate new features design. The Institute will in future receive an i creasing share of Admiralty tidal work, and h already been responsible for tide-predictions for sev Colonial and three Japanese ports. The theoretic work of the Institute has been actively continu during the past year, particularly in relation meteorological effects on sea-level, and durir October, November, and December 1923, daily for casts of these effects on the sea-level at Liverpo were supplied to the Marine Surveyor of the Mers Docks and Harbour Board, in time to be of practic value as supplementing the information given in t regular tide tables.

THE belief has been expressed that the airsh industry will pass with the ZR3 from Germany the United States, where the Goodyear Tyre ar Rubber Co. has purchased all rights. On the oth hand, the experience gained in the design, constru tion, and test of the latest model will go far to tid Germany over the duration of the restrictions impos by treaty. Comparison with the first really successf Zeppelin shows the progress in design.

	Completed.	Volume ($m.^3$).	Total lift in tonnes.	Disposable load in tonnes.	Power (kw.).	Max. speed (km./hr.)
LZ3 .	1906	11,500	12·5	3·5	2×65	45
ZR3 .	1924	70,000	81	41	5×300	140

The following table gives the performance of 7 German naval airships:

Cause of writing off.	Number.	Av. life (months).	Av. service flights.
Enemy action . . .	24	6	15
Accidental fire . . .	12	7½	17
Weather and mishaps . .	22	7	12
Worn out	5	19	36
Dismantled after Armistice	9	16	21
Total . .	72		

Latterly, an airship coming within range of fightin aeroplanes met with almost certain destructior For commercial airship transport, eliminating wa and fire risks (on the assumption of adequate supplie of helium), and allowing for the effects of the Armistice a probable useful life of much less than 18 month and 32 voyages is indicated. The receipts woul clearly not pay capital and running costs without

ery subsidy. It will be of fundamental interest observe whether the ZR3 falls short of or improves these figures.

THE Public Works Branch of the Department of Industries and Labour of the Government of India has issued a second supplement to the Triennial Review of Irrigation in India 1918–1921 (issued in 1923), containing an account of State irrigation works carried out in the year 1922–3. From this we learn that, averaged over the plains of India, the rainfall was 5 per cent. above normal. The chief features of the distribution of the monsoon rainfall during the year were (1) the excess in the tract of country extending from the east and north Punjab to Orissa and Bengal, and (2) the deficiency over the Peninsula, excluding the west coast, and in the region of north-west India comprising the Rajputana desert and the country to the west. During the year 1922–23, the total area irrigated by all classes of works in India, excluding the Indian States, amounted to 81 million acres, which exceeds the average area irrigated during the preceding three years by about 2 million acres, and the record area of 28·1 million acres irrigated in 1919–20, by more than 180,000 acres. The largest irrigated area was in the Punjab, in which province $10\frac{3}{4}$ million acres were irrigated during the year. Next came the Madras Presidency with $7\frac{1}{8}$ million acres, followed by Sind with $3\frac{2}{3}$ million acres and the United Provinces with $2\frac{2}{3}$ million acres. The total capital outlay, direct and indirect, to the end of the year 1922–3 on irrigation and navigation works, including works under construction, amounted to Rs.84,57 lakhs, the gross revenue to Rs.10,06 lakhs, and the working expenses to Rs.3,85 lakhs. The net return on capital was, therefore, 7·3 per cent. From the crop returns, 13 per cent. of the total cropped area was irrigated by Government irrigation works, and the estimated value of the crops so irrigated amounted to nearly $1\frac{3}{4}$ times the total capital expended on the works, a very striking testimony to the value and efficiency of the latter.

THE September number of the *Scientific Monthly* contains an interesting article by Dr. Paul D. Foote, of the Bureau of Standards, on old and new alchemy. The old alchemists were of two types—the precursor of the modern "successful oil-stock promoters," and the persevering predecessors of the modern chemists. Mediæval alchemy was a logical consequence of the theory of Aristotle that all matter is composed of one primary matter, on which different forms could be impressed; modern alchemy is an equally logical consequence of the hypothesis that matter is composed of two primary substances, negative and positive electricity, the grouping of the particles of which, the electron and the proton, into different forms, is the study of the modern science of atomic structure. Dr. Foote describes the recent theories of matter and points out their bearing on the problem of the transmutation of the elements. The experiments of Rutherford on the disintegration of the nitrogen nucleus, for example, by α-rays, have to some extent removed the problem from the realms of pure speculation. The yields are still meagre: if all the four and a half billion billion α-particles from 1 gram of radium and its products in one year were projected into an aluminium target, the hydrogen liberated by the disruption of the nuclei would occupy 1/1000 cubic millimetre.

A FULL report of the conference held in July last to consider the most effective means of securing the adoption of decimal coinage and the metric system appears in the September issue of the *Decimal Educator*, published by the Decimal Association. Representatives were present from Great Britain, the Dominions Overseas, and the United States, and it was resolved to urge the Government to appoint a committee to consider the advisability of making the penny one-tenth of the shilling, and to get rid of the confusion introduced into the measurement of volume by the change from the wine gallon to the Imperial gallon in Great Britain a century ago, without consultation with America. The conference suggested that the two gallons now in use should, by co-operation with America, be made identical and equal to four litres, so that the quart would be exactly a litre.

AN account is given in *The World's Health* for August (the organ of the League of Red Cross Societies) of the Papworth (Cambridge) village settlement for tuberculosis by the Director, Dr. Varrier-Jones. The colony numbers 196 persons. Patients are admitted in all stages of the disease, and the work they do is graduated according to their capacity. There is no limit to their length of residence, and they are encouraged to settle permanently with their families. It is thus possible for patients whose working capacity is below normal to continue doing part-time work for many years, instead of having to give up entirely in competition with the outside world. Dr. Varrier-Jones holds that this procedure prolongs life and renders it happy and useful, as well as being a sound business proposition.

THE Minister of Health has appointed the following committee to deal with the question of the supply of morphine and heroin to drug addicts: Sir Humphry D. Rolleston, Bt. (chairman); Sir William H. Willcox; Mr. J. W. Bone; Dr. R. W. Branthwaite; Dr. G. M. Cullen; Prof. W. E. Dixon; Dr. J. Fawcett; Mr. A. Fulton; Mr. J. Smith Whitaker. The committee is "to consider and advise as to the circumstances, if any, in which the supply of morphine and heroin (including preparations containing morphine and heroin) to persons suffering from addiction to those drugs may be regarded as medically advisable, and as to the precautions which it is desirable that medical practitioners, administering or prescribing morphine or heroin, should adopt for the avoidance of abuse, and to suggest any administrative measures that seem expedient for securing observance of such precautions." The joint secretaries of the committee are Dr. E. W. Adams and Mr. R. H. Crooke, Ministry of Health, Whitehall, S.W.1, to whom all communications should be addressed.

IN addition to the awards of the Institution of Civil Engineers for papers announced in NATURE of October 4, p. 513, the Council has awarded a Telford Premium

to Prof. Louis N. G. Filon (London) and an Indian Premium to Mr. F. C. Temple (Jamshedpur, India).

THE Institute of Metals programme for the session 1924–25 covers the work not only of the parent Institute, but also of its six branches located in various metallurgical centres. More than thirty lectures dealing with various phases of non-ferrous metallurgy are enumerated in the programme. Prof. H. A. Lorentz is to deliver the annual May lecture. Copies of the programme can be obtained from the secretary of the Institute, Mr. G. Shaw Scott, 36-38 Victoria Street, Westminster.

AN attractive list of free popular lectures to be delivered on Saturday afternoons at the Horniman Museum, Forest Hill, has just been issued. The lecture hour is 3.30, beginning on October 11, and the subjects of the lectures are "The Development of Modern Radio Communication," "Cornish Scenery and its Causes," "Social Life among Insects," "Some Famous Pharaohs," "The Amulets of Ancient Egypt and of Modern London," "Evolution and Darwinism," "Prehistoric Man and the Land of Lyonesse," "The Eggs of Animals," and "The Glory that was Thebes." No tickets will be required.

THE Chadwick Public Lecture programme for this autumn includes lectures in London on "Defective Hygiene and Child-Life," with special reference to the effect produced on growth and development of children by town dwelling and slum areas, by Dr. Lawson Dick; "Rats," by Mr. Mark Hovell; "Smoke," with a review of its causes, its effects on vegetation, fabrics, masonry and metal work, and its influence on health and the death-rate, by Prof. J. B. Cohen; and "Ante-Natal and Post-Natal Child Physiology and Hygiene," by Dr. W. M. Feldman. Further information about these lectures can be obtained the secretary of the Chadwick Trust, Mrs. Aubr Richardson, at 13 Great George Street, Westminst

MESSRS. J. and A. Churchill announce for public tion early next year a "Dictionary of Perfumery by E. J. Parry, which will deal with the raw materia of the perfumery trade and with allied subjects fro the points of view of the chemist, the manufacturer a the user. The work, which will be in two volume will contain special signed contributions by Messrs. A. Marrin, C. T. Bennett, T. H. Durrans, M. Dewhirs A. Garden, M. Salamon, and W. H. Simmons.

MESSRS. Thomas Murby and Co. are publishi shortly "A Handbook of the Geology of Ireland by the late Prof. G. A. J. Cole and T. Hallissy, whi is based on Prof. Cole's contributions to "T Handbook of Regional Geology," a German public tion. Another work in the same publishers' list announcements is "Useful Aspects of Geology," Prof. A. J. Shand, which aims at giving an account the various ways in which a knowledge of geolo can be turned to use, and at showing where to go f fuller information on each particular subject.

MESSRS. Ernest Benn, Ltd., announce for ear publication, under the title "Science and Labour the principal papers read at the Conference Science and Labour at the British Empire Exhibitio in May last. The subjects dealt with include T Place of Science in Government; Scientific Researc in Relation to Industry; The Co-operation of Scien and Labour in Production; Science and the Huma Factor, and Science in Educational Organisatio Among the contributors are Lord Askwith, Sir Richar Glazebrook, Sir Richard Gregory, Mr. Hugo Hirs Sir Thomas Holland, Sir Oliver Lodge, Sir Arth Newsholme, and Mr. Sidney Webb.

Our Astronomical Column.

THE TOTAL SOLAR ECLIPSE OF JANUARY 24, 1925.—The Journal of the R.A.S. of Canada for August–September 1924 contains an interesting article on this eclipse by R. M. Motherwell, of the Dominion Observatory, Ottawa, illustrated by a map of the track over Canada and the United States.

The eclipse comes at a bad season of the year, with a rather low sun, and the weather prospects are poor; but it is visible in a very populous region, including the observatories of the University of Toronto, of Columbia University, and of Vassar College, so that the most is likely to be made of the occasion. Portions of all the great lakes lie within the zone of totality; Niagara and Buffalo are near the central line. New York is just outside the southern boundary.

Totality lasts nearly two minutes on the central line. A large partial eclipse is visible throughout the British Isles. In the Western Hebrides the solar crescent left uncovered will be only some 8″ in width, but the sun will be too low there for any useful work.

This eclipse is a recurrence after the triple Saros of that of December 1870 visible in South Spain, North Africa, and Sicily. It was interesting from Prof. Young's discovery of the reversing layer, and the beautiful coronal photographs obtained by Mr. Brothers.

PROF. LA ROSA'S THEORY ON THE CAUSE OF STELLAR VARIABILITY.—Prof. La Rosa's suggestion that stellar variability may be explained on the ballistic theory of light was recently noticed in this column. The theor supposes that light follows the law of projectiles, th total velocity being compounded of the velocity of th source and that of light, so that in the case of distant star revolving in an orbit, the light that leav the star in equal time intervals arrives in unequa intervals, thus causing an apparent light-variation.

Prof. de Sitter criticises the theory in Bull. Astro Instit. Netherlands, vol. ii. No. 57, on the ground tha since the number of waves of any definite length tha enter the eye per second would be altered in the sam ratio as the light-intensity, an enormous Dopple shift, far beyond any actually observed, would resu if the theory were true.

Prof. La Rosa replies to this criticism in *Astr. Nach* No. 5319. He notes that his theory is not really wave-theory but a corpuscular or "quantum" one Still it is convenient to use the language of the wave theory. The point he lays stress on is that th spectral shift observed does not depend on the numbe of waves that enter the eye per second, but on th distance between crest and crest of these waves, an this distance would depend on the actual velocity o the star in the line of sight.

Probably most astronomers will consider that Pro La Rosa's theory is difficult of acceptance on othe grounds (notably the Michelson-Morley experiment) but that possibly the particular objection raised b Prof. de Sitter is not decisive.

Research Items.

A Congo Fetish.—Mr. H. V. Hall figures and scribes in a recent issue of the *Museum Journal* one e interesting and important wooden statuettes monly known as "nail fetishes" from Loango, coast district north of the Congo. The figure, t 32 inches high, represents a man standing with eft hand resting on the hip, the right raised as if to v a spear or inflict a blow with a bush knife. The of the head is left unfinished. It was formerly ed with a cap of hardened paste. Such caps were ste of varied composition, but usually containing nous elements. This paste embodied the fetish or power. It was sometimes attached in the of a casket to the abdomen or chest. These nes are said to have been employed when other s of detecting crime, such as the ordeal by poison, failed. In the course of a divinatory ceremony, power of the fetish is loosed against the offender by iring of a gun; but for certain offences a nail, times heated, is driven into the figure. It is also e in taking an oath in a solemn engagement; both nes strike a blow or two on the same nail, while each res the fetish to eat him up if he breaks his vow.

The Aborigines of Tasmania.—In the first R. M. uston Memorial Lecture delivered to the Royal ety of Tasmania last session, Sir T. W. Edgeworth id gives a useful summary of the geological ence of the antiquity of man in the Australian monwealth, with special reference to the Tas- ian aborigines (Proc. Roy. Soc. Tasmania, 1923). also records some new observations on the occur- e of stone implements, much resembling the er palæoliths of Europe, in the superficial deposits asmania. These implements have been found not in river drifts and lake beds of great antiquity, also in raised beaches from three to five feet above present sea level. Indeed, considering all the ence, "if aboriginal man in Tasmania was really emporaneous with one of the last great ice ages, he t have witnessed a sea level perhaps no less than feet lower than it is at present." He must have sed Bass Strait when it was either dry land or a narrow strip of sea; and as the dingo did reach Tasmania, the date of this crossing must e been anterior to the arrival of the Australian riginal in southern Australia. Implements have not e been discovered in Tasmania in association with remains of the large extinct marsupials, and Sir geworth David suggests that special search should made in the older sand dunes such as those of g Island, where remains of Nototherium have been d. He also thinks that further explorations are rable in the peat deposits and caves. Excava- as for harbour works and dredgings in Bass Strait uld be specially watched. Evidence of several ances and retreats of the ice during the glacial iod has already been noted in Tasmania, and there ns to be some hope that these may eventually be related with similar fluctuations in the northern isphere.

Scottish Anthropometry.—Every fresh analysis the anthropometrical characters of the people of tland emphasises the impossibility of discovering ial traits of any significance in a general sample of population. Since the first invaders made their tlements, fresh waves of immigration from outside l movements within the boundaries have tended to mp the original distinctiveness of the races. The neral population has become too mixed to be signifi- nt, so that the anthropologist must now rely only on chance of finding in certain localities pockets of individuals, who through a modified geographical isolation, or through a more effective isolation due to a persistent habit of intermarriage, have retained some indications of their origin. For this reason special value attaches to a small "Illustrated Catalogue of Specimens from Prehistoric Interments found in the North-east of Scotland," and contained in the Anthropological Museum at Marischal College, University of Aberdeen, of which Prof. R. W. Reid was the originator. The work, compiled with great care by Prof. Reid and his colleagues, contains an analysis of the human remains contained in some score of short stone-cists, along with descriptions of the beakers and other objects associated with the burials. The restricted area from which the interments have been drawn allows of easy comparison with the present-day population in the same district, which has recently been shown, by Dr. Tocher's researches, to be outstanding amongst the peoples of the Scottish mainland on account of the large proportion of brachycephalic individuals it contains. The Catalogue shows that the earliest settlers who have left traces of their habitation in the north-east of Scotland were markedly brachycephalic, with a brain-capacity similar to that of the average modern Scot, but of considerably smaller stature. They probably belonged to the broad-headed Alpine race which overflowed western Europe from the east during the Bronze Age. One notable exception is catalogued, a brachycephalic individual found at Catterline in Kincardineshire in 1923, whose brain-capacity was considerably greater than the modern average, 60 c.c. greater even than that of the large-headed Robert the Bruce, and whose stature was approximately 5 feet 8 inches. To this 3000 to 4000 years old race, or to subsequent immigrations from its continental settlements, may be attributed the predominant broad-headedness of the modern inhabitants of Aberdeenshire and the surrounding counties.

Protecting Wood against Termites.—Termites are particularly destructive to untreated wood in any form both in the United States and the tropics. Bulletin 1231 of the U.S. Dept. of Agriculture, by Mr. T. E. Snyder, is devoted to an account of tests of methods of protecting woods against the ravages of these insects. These experiments were conducted between 1912 and 1922, while supplementary data were obtained from inspections of treated timbers made from 1909 to 1922. The most effective preservative in protecting timber to be set into the ground was found to be coal-tar creosote. Impregnation by the "open-tank" method renders wood resistant to termite attack for at least 15 years. Impregnation by the full-cell process enables wood to resist these insects for at least 25 years, and this method is recommended for use in tropical countries. Brushing the creosote, in several coats, on timber will add from 2 to 5 years to its life. For interior woodwork, furniture, cabinet woods, etc., impregnation with zinc chloride, bichloride of mercury, sodium fluoride or chlorinated naphthalene is effective. Another protective method is to treat the hidden cheaper cores of furniture, cabinet woods, etc., with preservatives during manufacture, and then overlay them with veneers of termite-resistant woods. No species of tree apparently has wood which is absolutely resistant to termites, but among the most resistant woods are the teak and sal of India—a fact well known in that country; cypress-pine and camphor-wood of the Orient; greenheart of South America; redwood, western red cedar or giant arborvitæ, incense cedar, Port Orford cedar, yellow cypress, and species of

juniper of the United States. Wood-pulp products were also used in the tests and consisted of processed boards utilised in interior finish and as substitutes for lath, tiling, etc. These products were found to stand the tests best when crude carbolic acid or coal-tar creosote were added to them, although the odours are a disadvantage. It is stated that a large market for both crude and finished forest products could be found by American manufacturers in South America, and other tropical lands, provided satisfactory termite-proof products could be furnished.

PERMEABILITY OF LEAF CELLS.—Prof. H. H. Dixon describes a new method for determining the changes in the electrical conductivity of leaf cells, in Notes from the Botany School, Trinity College, Dublin, iii., 1924, 272 (see also Proc. Roy. Dublin Soc. xvii., No. 45, 1924). The method consists of placing a cut square of leaf on the horizontal arms of two plate electrodes, the latter being moistened with sap expressed from the leaf. It is found that temperature affects the permeability of leaf cells considerably, a rise of 10° C. increasing the conductivity (on an average) to 1·33 times as much. Further, changes of temperature of the order of 10° C. are shown to occur readily in insolated leaves, and hence considerable changes in permeability may be produced in a short time, which have doubtless an important bearing on the movement of materials in the leaf.

CARBON ASSIMILATION IN CONIFERS.—An interesting study of the ecology of carbon assimilation has been made by M. G. Stålfelt (Meddel. fr. Statens Skogsförsökanstalt, 21, 1924, p. 182). This deals with the rate of carbon assimilation of pine and spruce leaves in relation to temperature, light intensity, and the carbon dioxide content of the air. The measurements were carried out under natural conditions. The rate of assimilation falls off very markedly in older leaves at the higher light intensities, but in light intensities of about 30 per cent. of full sunlight, leaves of five years of age absorb much more carbon dioxide per hour than do young leaves (a year old). There is little or no assimilation below about 5 per cent. of full sunlight. The chlorophyll content of the leaves was also determined. For *Pinus sylvestris* the average was 15 mgm. and for *Picea excelsa* 10·6 mgm. in 10 gm. of fresh leaves. The numerous data might possibly repay further analysis. The author discusses xeromorphy in conifers in the light of his findings. A résumé in German is given.

THE STRUCTURE OF THE BASQUE PYRENEES.—In the *Boletin de la Sociedad Iberica de Ciencias Naturales* for 1923, Mr. P. W. Stuart-Menteath vigorously assails the recent work of the French geologists who have been engaged in revising the geological maps of the Pyrenees. While the official interpretation of the structure invokes thrusting on a large scale, Mr. Stuart-Menteath asserts that in the neighbourhood of the old mine of San-Narciso—a region that he has studied in great detail for many years—there is no evidence whatsoever of a thrust plane or of an abnormal sequence. Such evidence as has been put forward in support of the overthrust hypothesis is, according to this observer, due to a complete misreading of the stratigraphy. A formation, for example, that has been mapped as Carboniferous he claims as Flysch; and the underlying "mylonites" are, he says, ordinary conglomerates which locally contain Cenomanian fossils attached to pebbles of ophite. Collaborating with M. E. Fournier in the *Bull. de la Soc. Geol. de France*, xxiii. p. 102, 1923, detailed evidence is presented of the straightforward succession in and around the mine of San-Narciso. The mine itself has been abandoned and filled with wa for thirty years; but, despite this obstacle to obser tion, a band of limestone occurring beneath undoub Palæozoic rocks in the lower levels of the mine been considered as Cretaceous, and therefore as affo ing sufficient proof of an overthrust to bring controversy finally to an end. The authors, howev maintain their old view, based on actual investigati of the mine itself before it was closed down, that t limestone in question is of Devonian age, and that is normally surmounted by Carboniferous and Tri which in turn in a neighbouring syncline is follow by Cretaceous. It is to be hoped that the Fren geologists whose maps so flagrantly contradict t work of Mr. Stuart-Menteath will now discuss t evidence which has led them to disregard observations and conclusions.

HOURLY RAINFALL IN UNITED STATES.—T *Monthly Weather Review* for April has two articles variations in hourly rainfall at different places about the centre of North America which are co firmatory of each other. The first article, for Lincol Nebr., is by Mr. H. G. Carter, Meteorologist at t Weather Bureau. At Lincoln there is twice as mu rain in May as in October, and May has 50 per ce more hours with rain than October, but the avera shower in October lasts 25 minutes longer than t average shower in May. The data used in the pap cover 19 years, 1905–1923, and are for the months May to October only. For the entire period, abo 34 per cent. of the total amount falls during t twelve hours from 6 A.M. to 6 P.M., and about 66 p cent. from 6 P.M. to 6 A.M. In August 74 per cent. precipitation occurs during the night hours, while October the night precipitation is 53 per cent. a the day 47 per cent. The greatest rain frequen occurs in May, the least in August. The seco article deals with hourly precipitation at Topek Kans., and is by Mr. S. D. Flora, Meteorologist the Weather Bureau. Three-fourths of the pr cipitation falls in the six summer months and largely the result of thunderstorms. The hour wi the heaviest fall of moisture is near sunrise, and t hour with the least from noon to 1 P.M. The avera fall of rain at Topeka from 5 A.M. to 6 A.M. is mo than three times as great as from noon to 1 P.M more than 60 per cent. of the average day's precipit tion occurs between 6 P.M. and 6 A.M. The resul obtained will be welcomed by those interested rain insurance and by many others; some of t conditions which control the results would doubtle be similar to the conditions in Europe.

WINDS OF CENTRAL EUROPE.—Dr. Albert Defan of the Institute of Cosmical Physics of the Universit of Innsbruck, contributes an appendix (just issued) t the 1920 Yearbook of the Central Office for Meteor logy and Geodynamics, Vienna. The appendix co sists of a discussion of certain characteristics of th distribution of wind over the area which, before th War, was subject to the Austro-Hungarian monarch The data are derived from 372 wind-stations—236 Austria, 113 in Hungary, and 23 in Bosnia-Herzeg vina—and in most cases observations from ten yea are used; a list of the places and dates is given. Th collection of the data was undertaken during the Wa for war purposes. For each station the wind-observa tions for each of the twelve calendar months, at th separate hours 7 A.M., 2 P.M., and 9 P.M., were classifie according to the direction of the wind (8 compas points being used) and according to the intensity (i five classes). The summaries for the frontier regio were reproduced lithographically during the War, bu otherwise the data have remained unused. Th

pendix now summarises the data for the two months January and July (taken as typical of winter and summer) by means of eighteen maps showing by isopleths the distribution of various wind-characteristics. Six maps show the lines of equal frequency of (*a*) calms or light winds, (*b*) moderate winds, and (*c*) strong winds, for the two separate months, combining the results from the above three hours. Four maps show lines giving at each point the vectorial mean wind-direction for the separate hours 7 A.M. and 2 P.M. in January and July; four others show the lines of equal vectorial mean wind-velocity v for the corresponding times. Two maps give the lines of equal mean wind-velocity V, averaged without regard to direction, for the two months separately, combining the results for the three hours; while the last two maps indicate the value of the ratio v/V, which is evidently a measure of the constancy of direction of the wind at each place. It is impossible to describe these various maps briefly, but as regards wind-direction, they show that the wind is mainly westerly, though, particularly in the mountain regions, there are certain interesting disturbances of this general current.

The Ranges of the α-Rays from Uranium I and Uranium II.—Wölsendorf fluorspar shows pleochroitic haloes, due to the action of the α-rays from minute specks of radioactive substances. The phenomena are described by Dr. B. Gudden in the *Zeitschrift für Physik* of August 8. The haloes differ from those seen in mica, owing to the fact that fluorspar is bleached by rapid α-particles, and it is only at the end of the range that this action is reversed, and the material is coloured by their action. A section through the radioactive particle shows a series of fine circular zones corresponding to the different radioactive substances which have sent out α-rays. Measurements with different specimens show the haloes of uranium and uranium II (as a rather broad line), ionium, radium, polonium, radium emanation, radium A, and radium C^1. Although the haloes of uranium I and uranium II are not separated, it is possible from the measurements to determine the ranges in air of the particles from these substances, with an uncertainty of less than one per cent. The values obtained, 2·68 and 2·76 cm., are 1·5 mm. greater in the case of uranium I and 1·5 mm. smaller for uranium II than those previously regarded as correct. They show that the small values of the disintegration constant, λ, there are large variations from the linear relationship between log λ and log R_0, and they make the mean life of uranium II about fifty times as long as was previously suspected.

Electric Arcs with Non-Incandescent Cathodes.—Messrs. Stark and Casuto, using a brass anode rotated under the anode and so kept cool, were unable to maintain an arc; but Dr. H. Stolt describes experiments in the *Zeitschrift für Physik* of August 8 which show that if the disc is well polished, an arc can be produced. Still better results were obtained with cathodes of copper, silver, and gold, but there was no success with aluminium. The anode was a 0·3 cm. rod cut off at right angles to the axis, or with a little slope, and was held in a spring holder near the outer edge of the disc. The arc was struck by pressing the anode towards the rotating cathode against the spring, and at once releasing it. With small currents the disc could be touched with the finger at a point where the arc was in existence 1/100 sec. previously; and even with 10 amperes the temperature here does not appear to exceed 200° C. Spectroscopic examination of the arc throughout its length also showed no incandescence at the cathode. Very similar results were obtained by Nicol, who caused an arc to rotate between ring electrodes of copper in a radial magnetic field. Child and Bräuer assume that electrons are produced at the cathode by collisions of positive ions, but consider that a high temperature is necessary; apparently, however, this is not the case.

Influence of Magnetic Fields on Phosphorescence.—When an excited phosphore is heated, illuminated with light which does not excite it, or placed in a strong electric field, the rate at which it gives off light is increased, and the time during which it remains phosphorescent is diminished. In the *Annalen der Physik* for September, Dr. E. Rupp shows that similar results are obtained in a strong magnetic field; though the smallest field which gives a visible result is 17,200 gauss, using Zn Cu_α five minutes after excitation. The largest field available was 45,000 gauss, since larger currents could not be used in the magnet employed. Even with this field the effect was smaller than that produced with an electrostatic field of 10,000 volts per cm., and it is possible to employ very much larger electric fields than this. Thus it was not possible to observe all the phenomena obtained with electric fields by using magnetic fields, though the phosphore flashed brightly when the current was switched on, and this can be repeated once or twice, though with diminishing intensity. The extra light in the flash from a phosphore was found to be partly polarised perpendicular to the magnetic lines of force. This is more distinct with zinc manganese phosphores than with zinc copper phosphores, and there is no such phenomenon in an electrical field. F. Schmidt has explained the electrical phenomenon as being due to an alteration in the movement of the electrons, and to a rotation of the polarised atom pairs; the same explanation seems to hold for the magnetic action, since an electric field $E = vH$ is produced when magnetic lines of force pass through a space with velocity v. The polarisation of the light given off in this case seems to indicate that, in addition to this, the emission from the phosphorescent centres is directly influenced by the magnetic field, the orbits of the electrons being affected as in the Zeeman effect. The different atomic magnetism of the elements involved may also be of importance.

Rotatory Dispersion.—In the August number of the Journal of the Chemical Society, Lowry and Richards describe some measurements of the rotatory dispersions of octyl alcohol and octyl oxalate. A large number of wave-lengths was used in each case and the measurements were carried out with the greatest care. The results showed that the rotatory dispersion of octyl alcohol can be expressed completely by one term of Drude's equation. In the case of the ester, the results approximated to the inverse-square law of Biot, but could not be expressed either by that law or by one term of Drude's equation. The dispersion is therefore not simple, but complex.

The Production of Diamonds.—In the April-July number of the *Compte rendu des séances de la Société de Physique*, of Geneva, Duparc and Kovaleff describe an experiment in which carbon disulphide and "a metal easily sulphurised" were compressed to 8000 atm. for fifteen minutes. When the metal cylinder was dissolved in an acid a small residue, transparent, colourless, or slightly yellow, of irregular form, and capable of scratching glass, was found. It was birefringent and had a high index of refraction, but no density measurements were made. After a few days the residue fell to a powder. It is assumed that the region of stability of diamond at the ordinary temperature commences at a pressure below 8000 atm.

Ferrous Alloys Research: The Iron-Oxygen Equilibrium.

AT the autumn meeting of the Iron and Steel Institute held in September at the British Empire Exhibition, Wembley, an account was given by Dr. Rosenhain and some of his colleagues of an investigation of the alloys of iron which was begun by them rather more than a year ago under the auspices of the Ferrous Alloys Research Committee, which is the successor of the Alloys Research Committee of the Institution of Mechanical Engineers. The new Committee contains representatives of the Royal Society, the Institutions of Civil Engineers, Mechanical Engineers, Electrical Engineers, Naval Architects, and Mining and Metallurgy, and the Iron and Steel Institute. Under the auspices of this Committee, and with the concurrence of the Advisory Council of the Department of Scientific and Industrial Research, a beginning has been made upon a programme of work which is more ambitious, more difficult, and more expensive than anything which has hitherto been attempted. As Dr. Rosenhain points out in his introduction (Part I.) to the research, in spite of the large amount of scientific research devoted to the alloys of iron, much fundamental knowledge as to the constitution of the binary systems is still lacking. Most of the alloys hitherto investigated contain some carbon in addition to the special alloying metal, and this may, and probably does, have a profound influence on the equilibrium in question. Many of the most important industrial alloys contain three or more elements, and their composition has been arrived at largely by empirical methods. The precise influence of any particular element is largely a matter of guess-work. For this reason it is eminently desirable that the equilibria of the binary systems should be determined with the purest materials and the highest accuracy possible.

Messrs. Tritton and Hanson are responsible for Part II. of the research, which deals with the equilibrium of iron and oxygen, and a brief survey of their experiments will show something of the difficulties encountered in investigations complying with the above-mentioned standard. The iron was prepared by the method of Cain, Schramm, and Cleaves from an electrolyte containing pure ferrous chloride and sodium chloride. The product was satisfactorily pure except for a rather high oxygen content, due, so the authors think, to the formation of rust in the iron, which was deposited in a slightly porous form. Special attempts were made to prepare iron free from oxygen. At a later stage of the investigation a high-frequency Ajax-Northrup induction furnace became available, and the authors melted electrolytic iron previously purified by heating in hydrogen to 1200° C. in a vacuum of about 2 mm. of mercury, but the metal was not free from oxide. After various attempts, the best method was found to be to blow purified hydrogen on the surface of the metal during melting and for a period of fifteen minutes when molten. Even then the resulting metal was found to contain an amount of oxide estimated to represent about 0·08 per cent. oxygen. Both china clay and magnesia pots were used. It is to be gathered from the authors' paper that no iron prepared by them contained less than the above-mentioned amount of oxygen.

One of the greatest difficulties was to obtain pots and other refractory articles suitable for the work. Those made either of silica, china clay, or alundum will not hold molten iron containing much oxide for more than a few minutes, owing to the rapid attack on the pot by the oxide. Special pots had theref to be manufactured at the laboratory, and a u method has been developed, involving direct fus of the refractory in an electric arc, for producing p having internally glazed surfaces of great resista to chemical attack. The refractory (previou melted and powdered) is placed in a suitable recepta and spun in an electric arc in such a way as to fo in a few minutes a well-shaped pot having a body highly fired material, the internal surface of wh has been completely molten, leaving a glazed surf on the interior of the pot. Only in these was it fou possible to hold molten iron and iron oxide at t same time. For low-oxygen melts, china clay p were used, while for the higher oxygen alloys, bond pots of fused magnesia were found best.

Another difficulty which had to be overcome w

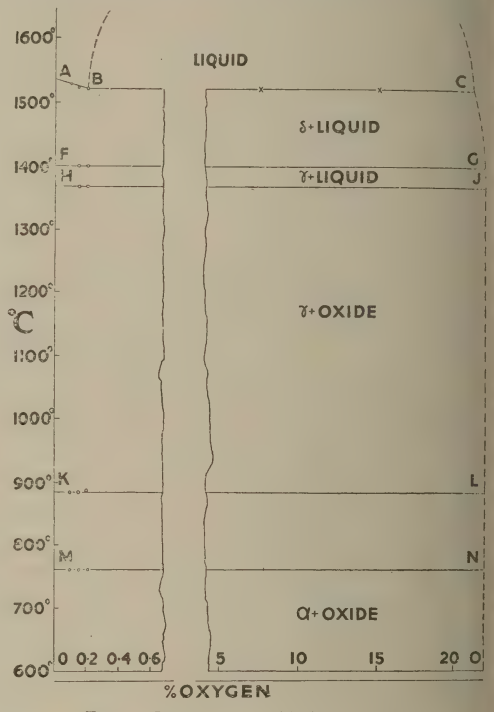

FIG. 1.—Iron-oxygen equilibrium diagram.

the contamination of the thermocouples, due appa ently to the penetration of the couple protector t the iron vapour. The best method was found to i to use a very low-sided pot and to blow nitrog across the surface of the melt. Contaminatio was worse in the pure platinum wire than in th platinum 10 per cent. rhodium alloy. According the authors substituted thermocouples of wires co taining 5 per cent. and 20 per cent. of rhodiu which gave a sufficient sensitivity for thermocoup work.

In spite of these improvements a certain amount contamination always occurred, so that the coup needed frequent testing and the removal of the co taminated portions of the wire. The freezing-poi of iron of the lowest oxygen content was found to 1535° C. referred to 1555° C. as the melting-point palladium. This is probably a very close approac to the freezing-point of pure iron, since, in spite the presence of oxygen, the slight slope of the liquid

re of the iron-oxygen diagram indicates that the ft of this amount of oxygen must be small. The e ng-point of the oxide stable at these tempera- r was found to be 1370° C., and that of the δ t ge point in iron 1407° C.

The authors have given the iron-oxygen equilibrium ram between 0·1 per cent. and 22 per cent. of ygen, represented by the compound FeO. This ram, which is reproduced in Fig. 1, is of con- rable interest. It shows that the percentage of ygen dissolved by iron in the liquid state does not ed 0·21 per cent., and that above this the liquid rates into two melts. The lowering of the ing-point of iron is, in fact, only about 8°. The l solubility of oxygen has not been exactly deter- ed, but is estimated to be about 0·05 per cent. will be seen from the diagram that oxygen is tically without effect on the δ, γ, and α change ts.

The authors have been able to prepare ingots ure iron-oxygen alloys, to roll them, and to sub- them to various physical tests. The maxi- m weight of ingot was about 450 gm. They e found that the low-oxygen iron (0·08 per cent.) be rolled perfectly easily both hot and cold, and the rolled material is ductile in a tensile test. ts, however, very brittle under notched bar impact tests; this may be due to the large grain size of the material which is facilitated by the purity of the metal in other respects. Ordinary normalising methods do not produce a small grain size in low-oxygen iron. With increasing oxide content there is a marked decrease in ductility. The authors have also carburised and case-hardened samples of iron of low and high oxygen contents, and have found that this can be done without difficulty. They conclude that the oxide particles appear to be practically unaffected by the process. This is certainly a matter of some importance.

Part III. of the research is contributed by Mr. Rooney, and deals with the estimation of oxygen in "pure iron." He has found that the best temperature for complete reduction of the oxide by hydrogen is between 1150° and 1200° C., and suggests that the problem of reducing it depends not so much on the facility with which the hydrogen can penetrate into the metal as on the ease with which the water-vapour formed can escape. Another method used is that described by Oberhoffer and Keil, which consists in heating millings with a proportion of an alloy of antimony (40 per cent.) and tin (60 per cent.), and collecting and weighing the water-vapour produced in the ordinary way. These two methods gave substantially identical results. H. C. H. C.

Seasonal Changes in Shell-fish.

MR. H. MUNRO FOX, in a paper published in the Proceedings of the Royal Society (B, 671) in January last, entitled "Lunar Periodicity reproduction," refers to vol. ii. of the Philosophical nsactions, published March 1667, by Henry Olden- g, Sec.R.S., wherein, at p. 419, may be found the owing question, forming one of a series comprised er the heading, "Inquiries for Suratte, and other cts of the East-Indies"—"Whether those shell- ses, that are in these parts plump and in season the Full Moon, and lean and out of season at the v, are found to have contrary Constitutions in East-Indies."

Modern zoology, through Mr. Fox, has answered s old-time question in detail; but there are e considerations that may be suitably advanced. is well known, in the earliest years of the Royal ciety, the promotion of knowledge by means of correspondency" with diligent persons in various rts of the world was encouraged in every possible y. Lists of inquiries were drawn up by fellows the Society, who were severally charged with the k of reporting such information as could be ured, or see that it was communicated to Olden- g. That zealous officer, with the prevision for ich he was famous, took care that such inquiries uld be placed on record in the Transactions, spective of replies. He desired to have "con- nations of the truth of these things from several nds before they be relyed on."

As regards the particular question which engaged . Fox's attention, it would appear that it was swered—though in the briefest fashion—by the rson to whom the whole body of inquiries was dressed, none other than Sir Philiberto Vernatti, en resident in Batavia. Sprat's "History of the oyal Society" was published in 1667, and in this prints the "inquiries" for the East Indies, but es further than Oldenburg, inasmuch as he supplies e original answers. It is matter for conjecture w it came about that Oldenburg only furnished e questions, whilst Sprat gave these, supplemented by the replies. The reply respecting shell-fishes was, "I find it soe here by Experience at Batavia, in oysters and crabs."

It is interesting to record the origin of the East India inquiries. So early as 1664, Vernatti had sent over a wooden case containing an "East-India present." The case was opened at a meeting of the Society, and at the same time the answers returned by Vernatti to inquiries which he had previously received (recommended to him by Sir Robert Moray), were read and ordered to be registered. Further, Moray was desired to write a letter of thanks for the double gift, and to take care that an order be drawn up for moving the East India Company by favour of the Lord Berkeley, that they would please to recommend such kind of inquiries to their correspondents in the East Indies, and take care of the conveyance of what should be committed to them for the Society.

Afterwards, Dr. Wilkins was desired to speak to his lordship, that he would, in the name of the Royal Society, move the committee of the Company to give their interest. Wilkins reported later that the Lord Berkeley had spoken with several of the Company and certain "very inquisitive men, now in town," who were thought able to answer queries. If unable, these queries would be put before their resident factors. Whereupon, Dr. Wilkins, Dr. Croune, and Mr. Colwall were charged with the prosecution of the matter. As an issue, towards the end of the year Dr. Wilkins acquainted the Society that some of the East India Company were ready to attend them, and it was ordered that the president (Viscount Brouncker), and as many of the committee for correspondence as conveniently could, should give them a meeting forthwith at some place to be agreed upon. Following these engagements, we hear no more of the undertakings until the year 1667.

In general connexion with the foregoing, it may be mentioned that in the Philosophical Transactions for 1669 a paper is printed entitled "On the odd turn of certain snails contrary to the solar turn."

Tests for Scholarships and Promotion.

IN the United States there are no scholarships offered to children passing from the primary to the secondary schools, and, except perhaps in New York, only a comparatively small number of scholarships are awarded for entrance into the universities. Moreover, the bases on which they are awarded are extremely numerous. These facts had to be borne in mind at the joint discussion of the Sections of Education and Psychology of the British Association at Toronto, in which eminent American men of science participated.

In Great Britain, on the other hand, scholarships are awarded on the results of tests, and it is therefore essential to investigate how well these tests—whatever their nature—are performing their function. At present, the most critical age is about eleven, when the child sits for the secondary school scholarship, but, as pointed out by Dr. Cyril Burt, the age of seven or eight, when children are promoted from the Infants Department to the Senior Department, is a neglected but crucial stage in the child's life, as his subsequent success in the scholarship examination may depend upon it. In fact, tests for scholarships to secondary schools are merely a particular case of tests for promotion. Thus, there may be tests for departmental promotion, for class promotion, for scholarships to secondary schools, trade schools, or even to the universities. Both in Germany and in the U.S.A. classes for gifted children have been formed, and it is argued that if psychological clinics are needed for selecting dull and stupid children, *a fortiori*, they are an essential prerequisite in selecting gifted children.

Prof. Whipple (U.S.A.) brought forward evidence to show that the selection of a class of bright children merely from those recommended by the teachers would have resulted in ignoring half of the brightest boys and girls; further, that pupils properly selected can accomplish two years' work in one, even under a mediocre teacher. Teachers are also likely to select for such work a number of pupils that ought not to be selected and that are certain to fail in the attempt to double their pace. It may be observed, in passing, that this question of determining what should be the acceleration of each pupil requires some caution, but, at present, it is rather beyond the province of this résumé.

Prof. Buckingham (U.S.A.) also showed that mental tests will prophesy with respect to the most capable children a rather high minimum of scholastic success, and will do this with high trustworthiness. This result was also shown to hold for university studer and it may be remarked that intelligence testing university students has become fairly general in t United States. Reference was made to investigatio carried out at Syracuse University, where a gr correlation of plus 0·60 between academic success a intelligence was obtained. It was found, howev that the relationship is closer among the more capal students and not so close among the less capable, that, for the purpose of selecting successful studen the intelligence test is more trustworthy than t correlation coefficient, depressed as it is by the presen of the duller students, would lead us to expect.

There is now a mass of evidence obtained by i dependent investigators in different countries whi enables an unprejudiced observer to draw certa broad conclusions, namely: (1) There exist at prese certain mental scales of proved use in assessing t innate mental ability of pupils. (2) Even the jud ments of capable teachers, when made independently such tests, are often untrustworthy and unjust. Wh these two conclusions are generally accepted, it seer difficult to avoid the further conclusion either th teachers should be trained in the use of such tests, else that all cases involving the assessment of t mental ability of an individual should be decided l qualified testers. Further, there is considerab evidence that children of high intelligence are al quite preponderantly children of good growth rat sound health, good social spirit, industrious, ar bitious, eager, and possessed of initiative and resourc fulness, who would unquestionably profit by reasonab educational acceleration and enrichment.

It is well worth while, however, to investigate wh should be the *reasonable* educational acceleration each pupil. It is often said that it takes all sorts make a world, and objection may be made to t draining of the brightest children from a class; ar further, that if the pupils in a class were as alike peas in a bag, that class would be dull indeed. B let it not be forgotten that the advocate of such procedure would be as rare and impractical as h antithesis who would abolish examinations altogethe even assuming that a psychologist could somewhe be found able to select such a class. The commo sense point of view would seem to be that of mo teachers, namely, that reasonable acceleration desirable, which means that more suitable treatme should be given to the brightest as well as to t dullest pupils for their own sakes, for the sake of t teachers, and for the sake of the community.

Vegetative Propagation in the Tropics.

PROBABLY no scientific problem more urgently needs attention in tropical agriculture than the establishment of standard yielding plantations from selected plants by methods of vegetative propagation. The commercial demand in the centres of distribution is always for a regular supply of produce of standard quality, and so long as the grower collects his crop from a plantation of chance selected seedlings of almost infinite variety, this commercial requirement cannot be met. With increasing competition, as supplies of tropical products arrive from new centres, as the development of tropical areas proceeds apace, it was certain that this point would gradually be grasped, and that, if cultural conditions permitted, the produce from vegetative propagation of standard varieties would oust the original variable supply from seedling stock, just as in Europe, and now in the United State vegetative propagation is the rule over all the va acreage supplying the world's needs in table fruit.

It is very instructive, for example, to read in Pro Hendrick's book, "The Peaches of New York," tha isolated experiments upon grafting peaches were mad in the United States from 1770 onwards, largely upo the repeated insistence of English colleagues on th value of the method; but in the period between 182 and 1860 the value of the uniform product thus avai able was realised, nurseries seemed to spring from th ground by magic, and whilst before that there wer millions of peach trees grown and few varieti recognised, in that period some 400 varieties wer carefully propagated and described, a number that b 1900 had reached a thousand.

ritish tropical possessions are as yet ill provided
the large and well-staffed experimental plantaics, on which alone the experimental work can be
ied out that is necessary before vegetative proaation can be resorted to upon a large scale with
taple crop. Unless provision is made for the
xerimental work and for the demonstration of the
e methods to the staffs of the commercial plantaics, a few decades may see British tropical prots ousted from the markets by the more trustthy produce from tropical areas developed by
er nationalities upon more scientific lines. In this
onexion the Ceylon journal, *The Tropical Agriurist* (vol. 72, No. 2), undoubtedly does good service
oBritish tropical agriculture by republishing the
ers by A. A. M. N. Keuchenius upon the vegetative
rpagation of tea and by Dr. P. J. S. Cramer upon
rafting in coffee culture, the latter being translated
rn the Dutch by H. L. Ludowyk, librarian to the
eylon Department of Agriculture. Thus is made
ailable to English readers the valuable scientific
rk carried out under Government auspices in the
Dtch East Indies.

The Java experiments upon vegetative propagation
the tea-plant were the natural corollary of the
section experiments carried out upon this plant at
d Government's Cinchona Plantations. Keuchenius
scribes no less than thirteen different methods
vegetative propagation which were tried, but
wilst only 2 per cent. of cuttings were successfully
opagated by placing branches, stripped of leaves,
moist sand, with crown-grafting an average of 74
cent. of successes was obtained, with rectangular
ch-budding about 87 per cent., and by upright stem
aering, in which roots were encouraged to arise above
ng in the bark by enclosing this region of the stem
soil held in a split bamboo, more than 50 per cent.
re successful.

Dr. Cramer's paper will well repay perusal because
its very general survey of vegetative propagation
the tropics, reference being made to the work at
e experiment stations at Lampongs and at Bangelan,
wich has been directed to exploit the possibilities
vegetative propagation of all the principal industrial
nts. He points out that the first experiments
on grafting coffee were initiated in order to protect
e highly valued Arabian coffee from eelworm
acks by placing them upon a resistant root
stem. He describes also the Klein Getas graft
it was known in Central Java, a valuable hybrid
nt which its owner, Dessauvagie, of course,
iled to reproduce from seed; it was perpetuated
the success of the owner of the Klein Getas estate
propagating it by grafting from, in the first place,
o branches which he succeeded in obtaining from
e original tree. It is unfortunate that in the transked account the word graft-hybrid, which has quite
adifferent connotation in recent literature, is frequently used for this propagation of a valuable hybrid,
otained by ordinary pollination means, by the
olinary method of grafting.

Dr. Cramer has been advocating grafting in the
se of coffee since 1907 in order to arrest the deteriorain that was manifest in Liberian coffee; he has had
a uphill task, but since 1914, when he took charge of
te Coffee Experiment Station at Bangelan, he has
en able to carry out his experimental plans upon
a extensive scale. He has now no less than 250
mall plots, grafted from separate selected parent
ees, 139 larger plots in which selected grafted forms
re being developed to provide scion shoots for larger
ectare plots; 30 hectare plots with 1100-1600 plants
each plot were planted at the end of 1918–19.
Records of the plots are being kept, the grafted plants
elding a regular harvest since the trees came into bearing. On a number of old plantations, trees have been cut back and grafted, the plantations thus being rendered a good deal more productive and the yield, of course, more uniform. This work has shown that the process of transformation to a grafted plantation can be carried out gradually, and the loss resulting from the crop one has to forgo is thus minimised.

University and Educational Intelligence.

ABERDEEN.—The following appointments to assistantships have been made: F. W. F. Hendry (agricultural chemistry); R. G. J. Fraser (natural philosophy); W. Niven (pathology); W. J. Ironside (veterinary hygiene).

CAMBRIDGE.—Prof. A. C. Seward, Master of Downing College, has entered into office as Vice-Chancellor of the University for the Academic Year 1924-5.

DURHAM.—Sir William Bragg, Fullerian professor of chemistry in the Royal Institution, opened the new College of Pure Science in October 1. After the ceremony, Sir William Bragg was given the honorary degree of D.C.L.

Applications are invited by Armstrong College for an adviser in agricultural mycology and an advisory agricultural economist. A British University degree is necessary; also some agricultural experience. Applications (10 in number) should be sent not later than October 20 to the Registrar, Armstrong College, Newcastle-upon-Tyne.

GLASGOW.—The King, on the recommendation of the Secretary for Scotland, has approved the appointment of Dr. H. H. Dixon, professor of botany in the University of Dublin, to be Regius professor of botany in the University in succession to Prof. F. O. Bower.

LONDON.—The following four candidates have been nominated for the by-election for the parliamentary representative of the University of London, in succession to the late Sir Sydney Russell-Wells: Sir John Rose Bradford (Conservative); Dr. F. G. Bushnell (Labour); Dr. E. G. Graham Little (Independent); Prof. A. F. Pollard (Liberal). The first three are medical men, while Prof. Pollard is professor of English history at University College. Polling, which will be by voting paper only, will take place on October 13-17, closing at 5 P.M. on the latter date. The results will probably be announced at 11 A.M. on October 18.

The vacancy in the Senate of the University caused by the death of Sir Sydney Russell Wells will be filled at the meeting of Convocation to be held on Tuesday next, October 14. There are three candidates, namely, Prof. Dame Helen Gwynne-Vaughan; Sir Josiah Stamp, the distinguished economist and statistician; and Dr. J. S. Bridges. Dame Helen Gwynne-Vaughan is professor of botany at Birkbeck College, and has for many years taken an active part in the work of the University. The XXth Century Society of London Graduates is strongly supporting her candidature, and has issued a circular, a copy of which has reached us, describing her many public services, and referring to her important contributions to botanical science. In her election address, Dame Helen remarks, in stating the main principles for which she stands:—" Situated at the heart of the Empire and in touch with unrivalled materials for research, the University has imperial responsibilities which can only be met by greatly increased provision for postgraduate study; places should be available not only for our own graduates

but for students from all parts of the Empire and beyond. This is especially the case in the Faculty of Science. The part which scientific workers can play in the life and government of the nation, and the value of their services are as yet insufficiently recognised. It should be the function of the University to educate the public in an appreciation of scientific discovery and to extend our knowledge by facilitating research."

A course of three free public lectures on "La Douleur, au point de vue des fonctions affectives et perceptives" will be delivered, in French, by Prof. H. Piéron, of the Sorbonne, at Bedford College for Women, on October 21, 22, and 24 at 5.15. No tickets will be necessary.

MANCHESTER.—An assistant lecturer in electrical engineering is required at the Municipal College of Technology. Forms of application may be had from the Registrar. They should be returned by, at latest, October 22.

APPLICATIONS are invited for two lectureships in pure mathematics, one senior and another, in the University of Cape Town. Ability to teach actuarial mathematics and statistics is desirable. Applications, in duplicate, must be sent (upon a special form) to reach the Secretary, office of the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2, by, at latest, October 28.

THE eleventh centenary of the University of Pavia is to be celebrated in May next, for it was in A.D. 825 that the University was made the centre for higher education in Lombardy. Part of the celebration will be the raising of a monument to Lanfranc, a member of the University, who afterwards became Primate of England; scientific workers will, however, more readily associate with the University the name of Volta, the distinguished professor of natural philosophy.

DR. M. C. RAYNER, joint author with her husband, Prof. W. Neilson-Jones, of "A Text-book of Plant Biology," and also author of a number of botanical papers, has been awarded a Theresa Seessel research fellowship for the year 1924–25 in the Graduate School of Yale University, for work in botany. The fellowship, which is of the value of 1500 dollars, was founded "to promote original research in biological studies," and involves residence in New Haven during the college year, October-June.

THE University of Bombay has received a gift of Government paper worth nearly 50,000*l.* for the endowment of university scholarships for Mohammedan students going to foreign countries for higher studies in medicine, philology, ancient history, Arabic, architecture, town-planning, and technological and industrial subjects, and in preparation for Government service. An interesting feature of the scheme is that the scholarships are to be considered as advances repayable with interest when the scholar obtains regular remunerative employment. The donors are the trustees of the educational trusts founded by Sir Currimbhoy Ebrahim and his daughter. We regret to record that Sir Currimbhoy, who has for many years been associated as a generous patron with numerous educational enterprises, especially Moslem schools, colleges, and orphanages, and the Institute of Science of Bombay, died on September 26 at the age of eighty-five, shortly after the announcement of this munificent gift.

Early Science at the Royal Society.

October 12, 1663. This meeting being appointed for the farther consideration of experiments fit to entertain his majesty with, several of the members present were charged to be curators of the following experiments—Mr. Boyle, To try the magnetical experiment of altering the polarity by repercussing the extremes of an iron rod, made red-hot and refrigerated; and also of destroying all the magnetism by striking it in the middle. To destroy the attractive virtue in a load-stone by heating it red-hot, whilst it keeps the directive virtue.—Dr. Ent, To bring in the anatomy of a lobster and an oister.—Mr. Hooke [among other experiments], To make an artificial eye; to try the casting of a picture on a wall in a light room; to make a hygroscope with the beard of a wild oat.

1664. It was mentioned that there was an instrument made for measuring the swiftness of the wind; and that Sir William Petty had observed that a wind-mill with an ordinary blast of wind turned so often, as to go after the rate of about sixty miles in an hour. He was desired to take care of these experiments, and to observe particularly the difference of the velocity of forced and of free wind; and to bring in an account of all.

October 14, 1663. Mr. Clayton related, that a lady having lost one of her teeth, a porter was hired, one of whose teeth was drawn by La Roche, and put into her mouth where it grew firm. This was confirmed by Dr. Whistler, who related that the same La Roche hit on this art accidentally, having once drawn out the wrong tooth of a countryman; for which mistake La Roche finding him extremely enraged, he told him that if he would have a little patience, he would put the tooth in, and make it grow again as firm as before; which he accordingly did, setting in the good tooth and putting the gums carefully about it.

October 15, 1662. Sir Robert Moray gave an account of his majesty's favour to the society, in declaring his pleasure, that no patent should pass for any philosophical or mechanical invention, but what was first put to the examination of the society.—He mentioned likewise a proposal likely to be speedily referred to them, of making iron with sea-coal.

October 16, 1661. Six balls of a like size were produced, one of lignum vitæ, one of stone, two of tin, and two of lead; to try their different velocity of sinking in water, or falling down in the air.—Dr. Pope made his experiment of breaking pebbles with his hand; which succeeded very well.—Mr. Greatoricks tried what he could do in the compression of water; but being not then prepared, he did not succeed.—Sir Robert Moray acquainted the society that he and Sir Paul Neile had kissed the king's hand, in the society's name; and he was desired by them to return their most humble thanks to his majesty for the reference, which he was pleased to grant of their petition; and for the favour and honour done them of offering himself to be entered one of their society.

October 17, 1666. Mr. Povey mentioned, that there was a certain moving sand in Suffolk, that was driven from one part of the county to the other, and had laid waste great parcels of land, and dam'd up a river; a full description of which he promised to procure with the first convenience.

1667. The experiment appointed for the next meeting, upon the suggestion of Mr. Hooke, was that of making the blood of an animal pass from one side to the other out of the vena arteriosa into the aorta, without passing through the lungs. Dr. Lower and Mr. Hooke were desired to take care of this.

Societies and Academies.

PARIS.

Academy of Sciences, September 8.—M. Emile Roux in the chair.—René **Maire**: The alpine vegetation of the Morocco Grand Atlas. Hooker and Ball, in 1871, made a rapid survey, expressed the view that there was no true alpine flora in the Great Atlas. The author's explorations in 1921, 1922 and 1923, in collaboration with MM. R. de Litardière and Humbert, show that there is a clearly characterised alpine flora, commencing on the north side at 3000 to 3150 metres, a short description of which is given.—Constant **Guichuin**: Quetelet's binomial law of probability.—**Wladimir Rylinski**: Michelson's experiment.—A. **Brodsky**: The corresponding temperatures of solid bodies.—**Georges Brus**: The oxidation of nopinene by permanganate. The yield of nopinic acid is increased by vigorous agitation of the non-miscible liquids, and by treatment during the process with a rapid current of carbon dioxide.—J. **Barthoux**: The massifs of Djebilet and of Rehamna (Morocco).—MM. **Rothé, Baroste, Bois,** Mlle. **Dammann** and Mme. **Hée**. Comparison between the explosion of Oppau and that of Nº 23 at Courtine.—E. **Ducloux**: Attenuation of the virulence of *Bacillus anthracis* (spore-bearing form). The immunising power of the attenuated bacillus. The attenuation was produced by a series of cultivations in a broth made from fish liver (*Gadus merlangus*). Experiments on the immunity produced in sheep are described.—G. **Guittonneau**: The production of ammonia from amino nitrogen by the microsiphonideæ of the soil. The results of experiments with glycocoll, alanine, leucine and tyrosine are given. There is generally some conversion into ammonia by the action of organisms, but the amino acids are not attacked with equal facility.—S. **Metalnikov**: The heredity of acquired immunity. Description of experiments on the grubs of *Galleria mellonella*. These were chosen because the eggs develop away from the mother, and into eight generations can be produced in one year. Evidence of the transmission of acquired immunity against the cholera organism M was obtained.

ROME.

Royal Academy of the Lincei, May 30.—V. Volterra in the chair.—F. **Severi**: Reduction of the principles of relativity to their logical and psychological elements.—A. **Piutti** and E. **Boggio-Lera**: Rare gases from volcanic exhalations.—L. **Sabbatani**: New pharmacological observations with sulphur. By simultaneous injection of sulphur and a reagent such as lead phosphate or silver iodide into the animal organism, it is shown that hydrogen sulphide is liberated immediately the sulphur comes into contact with the tissues.—Mario **Ferrari**: Datolite from Monte Cenpotréra (Reggio Emilia).—Teresa **Nocca**: Datolite from Rigollo (Province of Parma). Chemical and crystallographical data are given for this mineral.—Silvio **Ranzi**: Closure of the otocysts, development of the ductus endolymphaticus (or recessus labyrinthi, or aquæductus vestibuli) and its homology in the series of the vertebrates.—E. **Giglio-Tos**: Curious forecasts verified by experimental embryology.—G. **Fidda** and I. **Sciacchitano**: The polar groove and the fertilisation membrane in the egg of the sea-urchin.

SYDNEY.

Royal Society of New South Wales, August 6.—J. C. Anderson, president, in the chair.—W. R. **Browne**: Notes on the physiography and geology of the Upper Hunter River. The evolution of the valleys of the Upper Hunter and its tributaries is discussed. The main determining factors have been differential hardness of the rocks and submeridional Tertiary faulting, which has brought the soft coal-measure rocks against the harder Carboniferous strata. The upper portion of the Upper Hunter east of the fault-plane is probably a superimposed stream brought into being as a result of very extensive flows of Tertiary basalt, now largely eroded over a surface of Carboniferous rocks. The faulting may be continuous from about Werris Creek as far south as Branxton.

WASHINGTON, D.C.

National Academy of Sciences (Proc. Vol. 10, No. 7, July).—J. H. **Breasted**: Historical tradition and oriental research. Archæological discoveries in Egypt and the East generally point to the fact that Greek science and civilisation owe much to the Egyptians. Greek legends have, in many cases, been found to be based on fact. The nucleus of tradition is part of the surviving evidence of man's early history.—G. Y. **Rainich**: Second note: electrodynamics in the general relativity theory.—S. K. **Allison** and William **Duane**: The reflection of characteristic bromine X-radiation by a crystal of potassium bromide. Radiation from a molybdenum target tube operated at 63,000 volts was reflected from the 100 planes of the crystal. Evidence was obtained of the characteristic bromine K-series peaks.—Alfred W. **Simon**: Quantitative theory of the influence electrostatic generator. The treatment is mathematical and, it is claimed, can be applied to any static machine.—P. A. **Ross**: Scattered X-rays. Molybdenum K-lines scattered at various angles from heavy as well as light elements show shifts which are stated to be in accord with Compton's quantum theory of scattering.—George P. **Merrill**: (1) On a stony meteorite from Anthony, Harper County, Kansas, and a recently found meteoric iron from Mejillones, Chile. The former is classified as a grey chrondite much discoloured by secondary oxidation. The latter may be the original Mejillones mass which fell in 1874. (2) A meteoric iron from Four Corners, San Juan County, New Mexico. It is a breccia composed of fragments of a fine-grained pyroxenic rock with excess of coarse granular nickel-iron as cementing material.—M. T. **Bogert** and F. H. **Bergeim**: The constitution of Columbia yellow (chloramine yellow).—Cecilia H. **Payne**: A synopsis of the ionisation potentials of the elements.—Clyde E. **Keeler**: The inheritance of a retinal abnormality in white mice. Sections of the eyes of some albino mice showed the absence of visual cells, external nuclear layer and external molecular layers. The defect seems to be inherited as a Mendelian recessive.—W. R. **Miles**: Action of dilute alcohol on human subjects. Ethyl alcohol in dilute solution, broadly speaking, increases pulse-rate, metabolism and skin temperature, and decreases reflex irritability and efficiency generally. Accuracy is more affected than speed. The effect of alcohol appears to be related directly to the average concentration of alcohol found in the urine (samples taken at 30 min. intervals).

Official Publications Received.

Reprint and Circular Series of the National Research Council. No. 55: Science and Business. By John J. Carty. Pp. 8. (Washington, D.C.: National Academy of Sciences.) 20 cents.

Bulletin of the American Museum of Natural History. Vol. 51, Arts. 2 and 3: Further Evidence on the Structure of the Eosuchia; On the Classification of the Reptiles. By R. Broom. Pp. 39-76. Vol. 51, Art. 4: The Position of the "Sparassodonts"; with Notes on the Relationships and History of the Marsupialia. By Horace Elmer Wood. Pp. 77-101. (New York.)

Straits Settlements. Annual Report on the Raffles Museum and Library for the Year 1923. By C. Boden Kloss. Pp. 18. (Singapore.)

Memoirs of the Department of Agriculture in India. Botanical Series, Vol. 13, No. 1: Studies in Indian Tobaccos. No. 4: Parthenocarpy and Parthenogenesis in two Varieties of *Nicotiana Tatacum* L., var. *Cuba* and var. *Mirodato*, by Gabrielle L. C. Howard and Kashi Ram; No. 5: The Inheritance of Characters in *Nicotiana rustica* L., by Gabrielle L. C. Howard. Pp. 37+15 plates. Botanical Series, Vol. 13, No. 3: Studies in Indian Fibre Plants. No. 3: On the Inheritance of Characters in *Hibiscus Sabdariffa* L. By Albert Howard and Gabrielle L. C. Howard. Pp. 47-85+6 plates. (Calcutta: Thacker, Spink and Co.; London: W. Thacker and Co.) 2 rupees; 3s., each.

Memoirs of the Indian Meteorological Department. Vol. 23, Part 8: Frequency of heavy Rain in India. By Sir Gilbert T. Walker. Pp. 413-524. (Calcutta: Government Printing Office.) 3.14 rupees; 5s. 10d.

Conseil Permanent International pour l'Exploration de la Mer. Publications de Circonstance, No. 83: On *Chiridothea Entomon* (L.) in the Southern and Western Baltic. By Anton Fr. Bruun. Pp. 12. Publications de Circonstance, No. 84: Standard Net for Plankton Collections. By C. H. Ostenfeld and P. Jespersen. Pp. 16. Rapports et Procès-Verbaux, Vol. 33: Times of Entering of the Atlantic Salmon (*Salmo salar* L.) in the Rivers. By Osc. Nordquist. Pp. 58+2 plates. Bulletin Hydrographique pour les années 1920, 1921, 1922, 1923. Publié par le Bureau du Conseil, avec l'assistance de Martin Knudsen. Pp. 103. (Copenhague: A. F. Høst et fils.)

Proceedings of the South London Entomological and Natural History Society, 1923–24. Pp. xix+153. (London: Hibernia Chambers, London Bridge.) 10s.

University of Iowa Studies in Child Welfare. Vol. 3, No. 1: A Study of Hereditary and Environmental Factors determining a variable Character; Defective and Freak Venation in the Parasitic Wasp *Habrobracon juglandis* (Ashm.). By Dr. P. W. Whiting. Pp. 80. (Iowa City.) 1.25 dollars.

Diary of Societies.

SATURDAY, OCTOBER 11.

BRITISH PSYCHOLOGICAL SOCIETY (at University College), at 3.—Prof. C. Spearman: The New Psychology of "Shape" (Gestalt).—S. A. Hamid: Some Factors of Effectiveness in Mental ("Intelligence") Tests.

MONDAY, OCTOBER 13.

MEDICAL SOCIETY OF LONDON (Annual General Meeting), at 8.—Dr. E. M. Callender: Medical Memories.

TUESDAY, OCTOBER 14.

INSTITUTE OF MARINE ENGINEERS, at 6.30.—Indicator Diagram Lessons therefrom.

INSTITUTION OF HEATING AND VENTILATING ENGINEERS (at Caxton at 7.—H. A. Stirzaker: Safety Valves.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—M. O. The Pyrenees.

QUEKETT MICROSCOPICAL CLUB, at 7.30.—Major R. B. S. Sewell: Work of R.I.M.S. *Investigator* and Problems of Tropical O graphy.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Royal Automobile at 8.—Dr. W. R. Ormandy: Research (Presidential Address).

WEDNESDAY, OCTOBER 15.

ROYAL METEOROLOGICAL SOCIETY, at 5.—L. F. Richardson: (*a*) The Corona and the Diameters of Particles; (*b*) Photometric Obse on Clouds and Clear Skies.—L. J. Sutton: Notes on "Haboobs."

BRITISH SOCIETY OF MASTER GLASS-PAINTERS (at 6 Queen Square, at 6.30.—Sir Charles Nicholson: Architecture and Stained Glas

ROYAL MICROSCOPICAL SOCIETY, at 8.—J. E. Barnard and J. Smi Comparison Ultra-Microscope.—Dr. R. S. Clay and T. H. Court: Developments of the Hooke Microscope.—Prof. A. G. Horn Mounting with Venetian Turpentine.—J. Smiles and J. E. Par The Correction of High Aperture Dark-Ground Illuminators.

INSTITUTE OF CHEMISTRY (London Section), at 8.—The Positi Chemistry (Various Papers).

THURSDAY, OCTOBER 16.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30. Rohrbach: Large All-metal Seaplanes.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at —J. S. Jones: Hygrometry for Deep Mines.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Prof. Nunn: The Educational Philosophy of Gentile.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Pictorial Meeting.

CHEMICAL SOCIETY, at 8.—R. Lessing and A. L. Banks: The Infl of Catalysts on Carbonisation.—R. G. W. Norrish and Dr. E Rideal: The Photosensitive Formation of Water from its Elemen the Presence of Chlorine.—J. Kenyon, H. Phillips, and H. G. Tu Investigations on the Dependence of Rotatory Power on Chem Constitution. Part XXIV. Further Experiments on the W Inversion.—Dr. F. L. Pyman and E. Stanley: The Directive Infl of Substituents in the Glyoxaline Nucleus on substitution in Benzene Nucleus of Phenylglyoxalines—the Nitration of 2-ph glyoxaline and its Carboxylic Acids.

ROYAL SOCIETY OF MEDICINE, at 9.30.—Dr. W. T. Grenfell: Medicine Corner of the Empire.

FRIDAY, OCTOBER 17.

SOCIETY OF MEDICAL OFFICERS OF HEALTH (Annual General Mee (at 1 Upper Montague Street, W.C.), at 4.30.—Dr. R. A. Ly Idealism in Public Health.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur K Anatomy and Malformations of the Heart—(1) Specimens illustr the Evolution of the Human Heart.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—T. Th Baker: The Telegraphy of Photographs by Wire and Wireless.

JUNIOR INSTITUTION OF ENGINEERS (at Royal Society of Arts), at —R. P. Howgrave-Graham: High Voltage Electric Oscillations.

ROYAL GEOGRAPHICAL SOCIETY (AND ALPINE CLUB) (at Albert Hall 8.30.—Gen. Bruce, Col. Norton, Capt. G. Bruce, and Mr. Odell: Mount Everest Expedition.

SATURDAY, OCTOBER 18.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 4.—Sir Archibald Garrod: Harveian Oration.

PHYSIOLOGICAL SOCIETY (at Guy's Hospital).

BIOCHEMICAL SOCIETY (at Cambridge).

PUBLIC LECTURES.

SATURDAY, OCTOBER 11.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—R. P. G. Denman: Development of Modern Radio Communication.

MONDAY, OCTOBER 13.

UNIVERSITY COLLEGE, at 5.30.—Prof. E. W. Scripture: Researches Speech and Song.

WEDNESDAY, OCTOBER 15.

Living Religions.

FOR nearly two weeks—from September 22 to October 3—a Conference has sat in London to listen to the tenets of some of the principal living religions of the world as expounded by distinguished adherents. It was held on the initiative of the School of Oriental Studies and the Sociological Society. The Conference, it is believed, was the first of its kind and was intended primarily to be educative It aimed both at disseminating accurate information relating to the religions represented and at removing certain popular misunderstandings. Mohammedanism, Hinduism, Buddhism, Taoism, the religion of Sikhs, Jains and Parsis, and primitive religions were represented, for the most part by members of the British Empire. It thus affords some indication, imperfect perhaps, of the great variety of religious belief to be found within this one political organisation.

An exposition of religious dogma at a conference carries with it something of an academic atmosphere, and, however much it may bring out the contrasts of different systems of religious philosophy, it fails to give full emphasis to their moulding force in determining the practical attitude of those who profess them towards their fellow-men and towards life as a whole. The influence of religion may appear imponderable except in times of conflict and stress. Life in a modern community does, no doubt, obscure it, may even weaken it ; but for the majority of the inhabitants of the world, it is still all-pervasive and fundamental. This is more especially evident in the case of primitive peoples. It is on this account that study of primitive belief and ritual is an essential precedent condition of success in the administration of backward races.

It is not without significance that the religions of India should have taken a prominent place in the proceedings of the Conference. They rest upon a highly developed theological and philosophical basis ; they present marked contrasts ; and perhaps nowhere else is it possible to see more clearly the force of religious belief in determining the form and character of social organisation. In Hinduism the system of caste, with its rigid determination of social grades, the doctrine of asceticism, and the emphasis laid upon meditation as a form of religious practice, permeate every phase of Hindu society. The caste divisions, with the doctrine of untouchables and the specialisation of occupation, have proved, and are likely to continue to prove, an insurmountable obstacle to any lasting social and political unity. They have given a static character to social organisation which stands in the way of development.

The effect of religious belief, however, in the daily life of the people is even more clearly to be discerned when attention is directed to primitive conceptions, not

merely as they appear enshrined as survivals in the highly developed philosophical thought of official Hinduism, but in the popular religion, the traditional animistic beliefs, and the regard for the village deities of the mass of the population which were overwhelmed with the Aryan invasion but are still the predominant element in the popular religion. The significance of the survival of these primitive forms of belief lies in the fact that they still tend to keep alive the village community as the effective social unit. It is noteworthy that the modernist movements in India, which aim at a larger unity, seek to break down what, from the social if not from the philosophical point of view, have been the most persistent features in Hinduism. The reform movements in Hinduism, therefore, both Brahmo-Samaj, with its tendency toward universalism in its later developments, and Arya Samaj, with its militant nationalism, aim at ignoring differences of race and caste and seek to mould India into one people. In the same way the differences in doctrine of other forms of religion, whether Mohammedan, Parsi, Sikh, or Jain, are reflected in their social organisation. Yet if they neither observe caste nor practise asceticism in the strict sense of the term, they do not any the less hold themselves strictly apart. How deep is the line of cleavage can be seen in the bitterness of the conflict between Hindu and Moslem, which is repeatedly manifested upon occasions which might seem trivial to an outside observer. At the present moment the attempt at a reconciliation between the two bodies hangs upon an adjustment of their respective attitudes towards the cow, and whether it may be possible for the Mohammedans to devise a method of slaughter of this sacred animal which will not offend the susceptibilities of the Hindu.

The philosophical character of the sacred books, and the fact that information relating to Indian religion has been too exclusively drawn from literary sources, has tended to obscure the practical effect of religious belief in determining the form of Indian social institutions except in their more obvious aspects. But none the less in India, as in other parts of the world where religious beliefs conform to a primitive type, that attitude towards the hidden powers underlying material things which anthropologists call animism is a dominant factor in the form and content of social life. An instance at once suggests itself. The social organisation of the Todas depends entirely upon the sacred character of the cow; it is arranged to meet the requirements of the ritual of the dairy. An analogous case is to be found in East Africa, where the institution of royalty and the whole of the kingly ceremonial among the Bahima is based upon the sacred nature of the cattle and the dependence of their welfare upon the king. Even the diet of the people and their food taboos, whether temporary or permanent, are related to the sac sanctity of the milk and the care which must be taken protect it from the slightest danger of ritual uncleanne

It would be possible to add almost innumerable stances among primitive peoples in which the form a content of social institutions are directly dependent up the character of their religious beliefs. The widely spre totemic system in its various types, the matriarcha and the prominence given to the mother's brother all matters in which in the patriarchal system t father holds the authority, are instances striking their diversity from our own customs. But, as James Frazer has shown in "Psyche's Task" (Londo Macmillan and Co.), primitive religious ideas und lie some of the most important functions of mode civilised life. Taboos similar to those which are n observed in the islands of the Pacific lie deep root at the base of our ideas of property; the divine rig of kings can trace its ancestry to the sacred ch acter of the chief, whose power may rest either w the fact that he embodies the spirits of his ancesto or that by his power as a magician he can control t hidden forces of the world around. The primiti belief in magic has determined the forms of the la and the invocation of spirits, assisted by the admin tration of poison or other form of test, has grown ir the trial by ordeal out of which our judicial proced has developed, still retaining the administration of t oath, formerly a test and now a guarantee of the hones of a witness.

It may be asked in what sense the term "livi religions" has been applied in selecting the forms religious belief to come before the Conference which h just been held. An attempt to supply an answer the question has been made by Mr. Victor Branford in essay [1] which, although not an official publication, w issued as an interpretative study a few days before t Conference met. Mr. Branford, who is a co-worker wi Prof. Patrick Geddes, would apply the term only those religions which show signs of developing alo the lines of the larger modernism. As an instance his meaning he cites the case of Indore, where t ritual processions have been adapted, at the suggesti of Prof. Geddes, to subserve the needs of the ci in improved sanitation and housing. In the mode State, he beholds a vision of a cult in which the comple unification of the sciences and arts is directed to t cultivation of the highest faculties in man in a civ environment in perfect harmony with that end. The perhaps the matter may be left without too clo an examination of how far the place of religion in actual modern community falls short of this ideal.

Primitive Medicine.

Medicine, Magic and Religion: the FitzPatrick Lectures delivered before the Royal College of Physicians of London in 1915 and 1916. By Dr. W. H. R. Rivers. (International Library of Psychology, Philosophy and Scientific Method). Pp. viii + 147. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., Inc., 1924). 10*s.* 6*d.* net.

Had Rivers lived for a few more years, there is little doubt that this book would never have seen the light in its present form. The Fitzpatrick Lectures, which he delivered in 1915 and 1916, are now published practically as they were delivered, but Rivers intended, as Prof. Elliot Smith has pointed out in the preface, to make them the basis of a comprehensive treatise on primitive medicine; and to this end he had already collected an enormous bibliography. The loss to science is therefore incalculable; for Rivers was, just before his death, projecting another advance in knowledge, which only he, of British ethnologists at least, if not in the whole world, was capable of making. Shortly before his death, he said that he was going to make it his business to set out in proper form the doctrine of the biological analogy, which has been so discredited through its misapplication, but, nevertheless, is of the utmost importance to the proper understanding of the social process as a whole. With his incomparable knowledge of medicine, psychology, and of ethnology, he would undoubtedly have produced work that would have added a pinnacle to his fame. But this was not to be, and the world will have to wait until another shall arise capable of the feat.

This book has a twofold interest. In the first place, it is a piece of ethnological research which throws much light on the problem of the relations between medicine, magic, and religion, especially in communities of the lower culture. For this reason it will be valuable to the student, especially as much of the material has been collected by Rivers himself, partly in collaboration with W. A. M. Hocart, in Melanesia. The scene of action is usually placed in Melanesia, but in the latter part of the book a survey of the world is carried out which serves to give a comparative value to the result of his investigations. This line of work is likely to have a considerable influence on ethnological method in the future.

The second feature of interest in the book lies in the fact that Rivers was facing some of the consequences of the change of attitude towards the problem of accounting for the culture which any community possesses. Having broken away from the orthodox school of Great Britain, and taken his stand on the side of diffusion, he was forced to examine every fact that came under his purview from this point of view. The result is illuminating. It is, also, safe to say that had Rivers not adopted, in his "History of Melanesian Culture," the method of culture-mixture, by which he tried to show how various elements of culture might have arisen as the result of the intermixture of two or more cultural streams, it is probable that he would have moved much faster in the direction in which he was travelling than he actually did. Indeed, there is no doubt that it was this preoccupation with the problem of culture-mixture that prevented him for some time from realising the extent of the revolution he had caused. But, at the same time, there is not much doubt that he would have agreed ultimately entirely with the point of view of Elliot Smith. This is shown in his comments on the discoveries in San Cristoval made by Dr. E. C. Fox, whose book is shortly to be published.

The volume under notice consists of five chapters. Each of the four Fitzpatrick Lectures occupies a chapter, and the Rylands Lecture in 1919 on "Mind and Medicine" is published as the fifth chapter. The first chapter is occupied with the discussion of beliefs concerning the causation of disease among various Melanesian peoples. Peoples of low culture usually ascribe disease to the magical actions of some human being, or to some spiritual agency, which either enters the body of the victim, or else abstracts the vital essence and so causes disease. Sometimes minor ailments are ascribed to natural causes. A sorcerer who causes disease can act in one of three ways. He can project some morbific object or influence into the victim's body; he can abstract something from the body; or he can act on some part of the body, or some object which has been in contact with the body. The last case would be termed one of "sympathetic magic" by Sir James Frazer and his school of thought, the idea being that natives imagine that the two disconnected bodies are really in communication by means of "a kind of invisible ether." Rivers believed that this interpretation is mistaken, and that the "contagious magic" of peoples who practise such rites "rests not on any mystical belief in action at a distance, but on the belief that the sorcerer has in his possession part of the soul of another person, part of the vital essence of the person which he wishes to destroy" (p. 27). That is to say, the magical procedure of these peoples rests on a concrete, logical basis.

Then comes an interesting chapter dealing with diagnosis and prognosis, the bases of which are magical and religious. In this chapter Rivers is at pains to show that the religious element is far more important than is usually assumed, that the formulæ which form so constant a part of the magical rites are very often

supplications, appeals to higher powers, and not charms which are supposed to be efficacious in themselves.

As a result of the native theory of the causation of disease there has been produced, in certain places, an immense variety of specialisation. For example, in Eddystone Island of the Solomons, there is a degree of specialisation that puts Harley Street "in the shade." Practitioners are to be found there who deal exclusively with rheumatism, fever, epilepsy, insanity, and so forth; each has his own particular technique and knows nothing of the manner of treatment of other complaints—a "division of labour" *in excelsis*. Rivers lays great stress, also, on the part played in medical practice among peoples of low culture—in contrast, is it possible, with their more civilised brethren?—of suggestion. He suggests that the savage practitioner is less of an impostor than we are apt to believe, and, what is more, he goes so far as to suggest also that the modern quack is not necessarily always a humbug, but that he may have implicit faith in his nostrum.

The second half of the book is concerned with the problem of transmission of culture. Here Rivers discusses from this point of view the medical practice of various parts of the world, as well as different forms of medical treatment. He shows, for example, that two theories as to the causation of disease are widely held. One, which ascribes disease to the abstraction of the vital essence, is held in Indonesia, Papuo-Melanesia, and America. The other view, that disease is the result of possession, is found pre-eminently in India and Africa. Rivers comments: "If the phenomena of disease are much the same all the world over, and if the similarities of belief and action are due to the uniformity of the human mind, how comes it that men should have been led to these very different beliefs and why should these beliefs have different distributions?" Again he brings forward the case of remedies of what he terms the "domestic order"—massage, vapour-baths, venesection, cupping, and similar treatments, and comments thus:

"Highly as we rate our civilisation, it did not enable us to discover for ourselves practices which, according to advocates of independent origin, must have been discovered by the Melanesian and Papuan. We acquired our practices of bleeding and counter-irritation from the Greeks or Arabs, our massage from the French or other continental people, and our vapour-baths from the Turks and Russians. The civilisation of which we are so proud did not of itself suffice to teach us these remedial arts, but we had to acquire them by contact and mixture with other peoples. If we are to accept the teachings of those who believe in the independent origin of such practices in Africa, Asia, Oceania, and America, we shall have to accept the position that the savage or barbarous peoples who inhabit these co[n]ents and islands were somehow able to discover [t]hings which we, who think ourselves so greatly their superi[o]rs, were content to learn from other peoples" (p. 85).

Rivers then proceeds to discuss the mechanism of culture-transmission, and to show what modificati[o]ns may be produced during the process, taking medical practice to illustrate his points. This is one of the most important chapters in the book, revealing as it does, with the utmost clarity, the attitude which Rivers then adopted towards the general problem of the transmission of culture, the problem which is bound, in the next few years, to occupy most of the attention of ethnologists. He studies the factors which determine the survival value of an introduced element of culture, as well as the modifications which it undergoes as the result of introduction into a new environment.

In the course of this discussion, Rivers lays special stress on the factor of degeneration, which he certainly, so far as our knowledge goes, was the first to stress and to study in detail. He says:

"We are only now emerging from a period in the study of human society during which the factor of degeneration has been almost wholly neglected or greatly underrated, even in the case of the ruder phases of human culture"—adding, also, the characteristic caution: "In seeking to show how great a part degeneration has played, and is still playing, in the history of human society, we must be careful not to go to the opposite extreme, and overrate its frequency and importance" (p. 110).

The final chapter, "Mind and Medicine," is already familiar to many of the readers of NATURE. It is the result of the experience gained by Rivers during the War, when he had charge of men suffering from "war strain." Rivers was one of the first medical men in Great Britain to advocate and to clarify the views of Freud and his school concerning psycho-pathology, and in this chapter he adumbrates the application of the results of this work to the study of human society and its disorders, which certainly would have formed the great task to which he would next have turned his attention. His masterly treatment of self-knowledge, self-reliance, and suggestion in their social aspects is bound to have important repercussions in the domain of social psychology.

The reader of this work must certainly come away with the feeling that had Rivers lived for another ten years, so as to have been able to gather together the treasures which he had won in so many departments of knowledge, the science of anthropology would have been incalculably the richer. It is a tragedy that he should have gone just when his powers were coming to the full maturity, when he was at last coming into his own.

W. J. PERRY.

Relativity.

(1) *Théorie quantique des spectres. La Relativité.* Par Norman Robert Campbell. (Supplement à l'ouvrage: La Théorie électrique moderne; théorie électronique.) Traduit de l'anglais par A. Corvisy. Pp. 237. (Paris: J. Hermann, 1924.) 18 francs.

(2) *The Theory of Relativity: Studies and Contributions.* By Archibald Henderson, Allan Wilson Hobbs, and John Wayne Lasley, Jr. Pp. xiii+99. (Chapel Hill, N.C.: University of North Carolina Press; London: Oxford University Press, 1924.) 11*s.* 6*d.* net.

(3) *Teoria della relatività: saggio di una esposizione secondo il senso fisico.* Da Prof. Paolo Straneo. Pp. 161. (Roma: Dott. G. Bardi, 1924.) 15 lire.

(4) *Einführung in die Tensorrechnung.* Von Prof. Dr. Hermann Rothe. Pp. iv+179. (Wien: L. W. Seidel und Sohn, 1924.) 5*s.*

THE literature of the theory of relativity and of the subjects allied to it is increasing so fast that it is becoming very difficult for any one to keep pace with it, but several of the books in the collection under review present their subject in so novel and interesting a manner as to be well worthy of the attention of the most seasoned student of relativity. Little need be said of the first book (1), for it consists merely of the French translations of the two chapters on the quantum theory of spectra and the theory of relativity issued as supplements to Dr. N. R. Campbell's well-known book on "Modern Electrical Theory." It will be sufficient to state that the French translation expresses the meaning of the original text clearly and fully. It is well printed and commendably free from misprints—the few that remain are fairly obvious and unlikely to mislead the reader—and will certainly prove helpful to those French students of experimental physics to whom the more mathematical text-books on relativity by Becquerel and Galbrun are a stumbling-block.

(2) The second volume gives a succinct account of Einstein's special and general theories of relativity and of the physical experiments on which they are based and by means of which they can be tested. The first chapter of nine pages, by A. W. Hobbs, treats of some experimental anticipations; it is noteworthy for a very clear account of the theory of the experiment of Michelson and Morley. The second chapter of sixteen pages, by A. Henderson, gives a brief account of the special theory of relativity on conventional lines, whilst the third, by the same author, in forty-six pages deals with the general theory of relativity, including tensor analysis, and its consequences. Both chapters are remarkable for the clear enunciation of the fundamental principles postulated by Einstein and for the unusually complete and up-to-date treatment of the experimental tests of the theory, particularly the deflexion of rays of light and the displacement of spectrum lines. The fourth chapter of twenty-six pages, by J. W. Lasley, Jr., gives a complete, though concise, account of the curvature of manifolds according to the definitions of Gauss, Riemann, and Einstein, as an aid to the understanding of the geometry of the Einstein space. This may perhaps be regarded as the most distinctive feature of the book. Naturally a complete statement of the theory and its consequences cannot be expected in so restricted a space, but the treatment is clear and thorough so far as it goes. The book can be recommended as a brief summary of the theory, although it may, owing to its brevity, very well prove somewhat difficult reading for those who have not already acquired some knowledge of the subject from one or other of the standard treatises.

(3) Prof. Straneo's "Teoria della relatività" is conceived on unusual lines: its purpose is not so much to give a complete account of the theories of relativity, special and general, developed by Einstein and his followers, as to supply physical interpretations of the different stages of their development and of the various results deduced from them. In this respect it invites comparison with Dr. Campbell's supplement, but whilst the latter is written specifically for physics students commencing their study of the theory of relativity, the former appeals to a wider circle of readers, more especially to those who already have a considerable acquaintance with the theory in its mathematical aspects. To these it offers a most interesting and stimulating presentation of an aspect of the theory too often neglected in favour of a more formal treatment, and thus it fills a distinct gap in the literature of relativity. About ten pages are devoted to a sketch of prerelativity physical theories, sixty to the special theory of relativity, ten to the period of transition, and sixty-five to the general theory. In accordance with the plan of the work, mathematical developments, though of course not absolutely ignored, are relegated to the background, whilst particular attention is given to the exhibition of the physical meaning of the various steps in the analytical formulation of the theories and the methodical explanation of the arguments employed in their development.

The general attitude of the author is perhaps best characterised by two theses frequently insisted upon in the book. The first is that the theories of relativity are physical theories and therefore, like other physical theories, must be judged by their capacity for subsuming and explaining the facts of physical experience as a whole, rather than the particular effects so often insisted upon, such as the motion of the perihelion of Mercury, the deflexion of light by the sun and the

displacement of spectrum lines, all of which are on too minute a scale to afford decisive criteria for the acceptance or rejection of theories of so wide a range. The second thesis is that the theories of relativity afford an opportunity for, but do not absolutely compel, a revision of our fundamental ideas of space and time. For though they establish an entirely new relation between them and enable us to use the four-dimensional space-time continuum as a convenient system of reference, yet they leave us with so great a difference in character between the two concepts, that we need not renounce our intuitions of them as essentially different. This truly fascinating monograph offers so much that is new and suggestive within a narrow compass that it can be read by every student of relativity with great profit, be he mathematician, physicist, or philosopher; its translation into English is very much to be desired.

(4) "Tensorrechnung," by H. Rothe, constitutes the first part of a projected treatise on tensor analysis and is an excellent introduction to tensor algebra. It may very well be reviewed with the other books of this collection on account of the close connexion of its subject-matter with the theory of relativity. In about one hundred and eighty pages it deals with its subject exhaustively, but at the same time assumes so little previous knowledge of higher mathematics and is written in such a clear and full manner, that students with even a very slight mathematical equipment can be expected to derive considerable benefit from its study and to find it a great help towards the understanding of standard works on the general theory of relativity. In spite of the fact that complete generality is attained, particularly in the later chapters, the author has contrived, by a judicious and gradually progressive arrangement of his theoretical material and a free use of well-chosen and fully worked examples, to lead the reader onwards from the theory of manifolds of two, three, and n dimensions, by way of the theories of scalars and vectors, to the theories of tensors, linear vector manifolds, and tensor fields of the most general types.

In general, the author has restricted himself to algebraic methods, such as the processes of addition, multiplication, and contraction ("Verjüngung"), and has reserved the study of differential and integral processes for another volume. It is very unfortunate that the completion of the work was cut short by the premature decease of the author; but even in its present incomplete state the book, in so far as it constitutes a complete treatise on tensor algebra, supplies a distinct want and forms one of the best introductions known to the present writer to a difficult and important subject. Like Straneo's work, it is well worthy of translation.

Aeronautical Science.

(1) AN obvious need in aeronautical literature is [a] book giving a reasonably competent accou[nt] of the principles of aviation, and not merely popular [and] spectacular on one hand, but not containing mass [of] of technical detail of an engineering or mathematic[al] character on the other. Messrs. Hart and Laidle[r]'s book is an attempt to provide for this need: it [is] intended primarily for young students among t[he] aircraft apprentices in the Royal Air Force. T[he] mathematical equipment of such readers is necessari[ly] slender, and the authors do not use any more advanc[ed] mathematics than elementary algebra and trigon[o]metry, with a few exceptions where the calcul[us] notation has had to be employed. It may be said [at] once that the book seems at least to be a very goo[d] attempt in a new direction. It is pleasantly writte[n] fairly full but not too big, comparatively cheap an[d] nicely got up, with numerous interesting illustrations.

There are three parts. The first is devoted t[o] historical and mechanical introduction. Part ii. give[s] the elementary principles of flight. Part iii. dea[ls] with the structure of the aeroplane, its parts, the engin[e] instruments, etc.

The historical portion of Part i. is a survey of th[e] development of aviation from the earliest times to th[e] present day. A lot of space is devoted to Leonard[o] da Vinci, while the work of the last twenty years i[s] dealt with very summarily—a rather serious error [in] perspective. The mechanical portion consists of [a] brief survey of the most important facts and formul[æ] of elementary mechanics, a useful reminder of thing[s] that presumably the student knows already: other[-]wise it can be of very limited utility.

In Part ii. the authors, after a brief reference to th[e] ornithopter and helicopter, turn to the main topic of th[e] book, namely, the aeroplane. The aerofoil is introduce[d] and its various characteristics. A really gallant effor[t]

is made to explain stability without the use of mathematical analysis, while control, manœuvres, and stunts complete a particularly successful and brief statement of the aeroplane and its motions in about 90 pages of print. Part iii. discusses the air-screw, graphical statics of aeroplane structures, and all the topics associated with the structure and manœuvring of aeroplanes. An excellent feature of the book is the large number of easy exercises, mostly numerical, to which answers are given. We can have no hesitation in recommending this excellent book to all students who wish to gain an elementary knowledge of the aeroplane. We would suggest, however, that in a later edition some effort should be made to justify the epithet "aeronautical." In its present form the book is really "elementary *aeroplane* science," and not "*aeronautical* science." The student would understand aeroplane flight much better if he had side by side with the theory of the aeroplane a brief and equally competent account of the airship and the balloon: the contrast in sustentation and the analogy in control would be eminently educative.

(2) From time to time we are allowed a peep behind the scenes and told of the progress made in the designing of helicopters in Great Britain and elsewhere. While it may be doubted whether the special encouragement given to this type of aerial locomotion will be justified by events, the attempt to produce efficient and stable machines on the helicopter principle will be not only a practical achievement of great significance, but will also represent a source of useful information that will have its repercussion on other branches of aeronautical study and practice.

M. Margoulis attacks the problem of the helicopter from its fundamental aspects, *i.e.* he bases his book on the study of the air-screw in its most general form. He first takes the case where the plane of rotation of the screw is perpendicular to the direction of motion, paying particular attention to the fixed air-screw. He then uses the results of observations made at St. Cyr, at the National Physical Laboratory, and by Riabouchinsky, to discuss the general case in which the plane of rotation makes any angle with the direction of motion. The results are applied to the helicopter in the form of an aeroplane, with air-screws rotating round vertical axes for purposes of sustentation when the horizontal speed is small or nil. Vertical flight and horizontal flight are discussed separately, and then the case of general flight is considered.

(3) M. Lafon's book has a twofold object. We have first a brief and interesting account of the naval captive balloon, with notes about its manipulation, "first aid" in connexion with accidents to the balloon or its attachments, meteorological notes, etc. This occupies 70 pages. The remaining 160 pages are devoted to "études beaucoup plus ardues," *i.e.* investigations of an engineering or mathematical character. This review must necessarily deal mainly with the latter.

First we have the theory of cables used with captive balloons, including the effect of wind. The author is clearly not a professional mathematician (it is to be hoped that non-mathematical readers will not misinterpret this remark), and the result is that he devotes a considerable amount of space in doing clumsily what can be done much more conveniently otherwise, and what indeed is fairly well known to such as have studied the forms of heavy chains. Interesting conclusions are reached when the wind is taken into account. The form is, of course, not that of the uniform catenary. If the weight is neglected M. Lafon gets a parabola with horizontal axis, as should be obvious *a priori* in view of the assumption made that the pressure of the wind is horizontal and proportional to the vertical projection of an element of cable. In general we have complicated curves (*not circles*, the author points out!), and it is of interest that the balloon can be in advance of the cable by the latter becoming vertical at some point below the balloon.

A topic to which the author directs special attention is one of tactics. The chief duty of the aerial scout is to give information as to the disposition of enemy ships. He must therefore observe, and this entails following an enemy ship at constant distance from it. We get the following problem in kinematics: A body moves in a given straight line (say) with given speed; a second body has given speed and is to move so as to be always at the same distance from the first: find the curve described by the second body. The author calls such a curve a "courbe encerclante"; he discusses the problem in great detail with tables and charts for the cases where the ratio of the speeds is 2 and 1·6 respectively. These and other matters form an interesting *mélange*, even if the author's claims to originality are occasionally rather feeble.

(4) The results of classical hydrodynamics are clearly not applicable to real problems, for obviously the statement that a sphere may move uniformly through a liquid without any resistance is at variance with the facts. Hence in the discussion of fluid resistance some departure from classical theory is required. Three main lines of departure have so far been suggested, and to some extent developed. In the theory of discontinuous fluid motion it is assumed that when a solid moves through a liquid there is a body of liquid behind the solid moving with it, while there is a surface of discontinuity separating this liquid from the remaining liquid where the motion is different at different points, and follows the laws of classical hydrodynamics. This theory has been developed in two dimensions by

Kirchhoff, Rayleigh, Mitchell, Greenhill, Levi-Civita, Cisotti, Villat, and others, while a suggestion for three-dimensional work on this theory has recently been made by Volterra. The second line of departure is the introduction of viscosity. The investigations made by Stokes have been extended by Rayleigh, Lamb, and others too numerous to mention, while the ideas of Oseen and his followers have led to interesting developments. Great promise attaches to the work of Bairstow and his assistants; a certain number of results have already been published.

The third line of departure from classical hydrodynamics is the subject of the present book by M. Roy. It is well known that d'Alembert's paradox, namely, that a body moving steadily through a frictionless liquid experiences zero resultant thrust, is true only if there is no circulation. When circulation exists we get a non-zero resultant thrust, as can be easily seen in the case of a circular cylinder. About twenty years ago a remarkable theorem was proved by Joukowsky, namely, that in two-dimensional steady motion there is a resultant thrust proportional to the density, to the relative velocity of stream and body, and to the circulation, in a direction perpendicular to the relative velocity: this thrust is quite independent of the shape of the cylindrical section.

It was very soon suggested that this theorem could be used to explain the remarkably high values of lift obtained with cambered aerofoils. As a matter of fact, similar suggestions were made on general lines by Lanchester in Great Britain, but his ideas were not followed up by any mathematical investigations. It was left to Kutta and others to apply mathematical analysis to this idea. At first artificial shapes were dealt with, like circular arcs, but during the last few years considerable progress has been made by a very active school of workers at Göttingen under the direction and inspiration of Prof. Prandtl—so much so that the theory is "popularly" known as the Prandtl theory. Considerable success has been obtained also by Glauert in England.

M. Roy gives a brief account of the method and of its chief applications, based on what is called the "linear theory," *i.e.* the theory in which the difference between the motions of any two particles of liquid is assumed small compared to the relative velocity between the liquid and the rigid barrier, so that only the first power of this difference is taken into account. The book is interesting and useful, but occasionally rather obscure, and difficult to understand. The main notion is, however, quite simple, and honours students in mathematics should certainly be introduced to it in preference to so many merely formal results included in orthodox courses on hydrodynamics. S. BRODETSKY.

Our Bookshelf.

Contributions to the Biology of the Rotifera. By Wesenberg-Lund. 1: The Males of the Rotif (Kgl. Danske Videnskabernes Selskabs Skrift Naturvidenskabelig og Mathematisk Afdeling, Række, IV. 3.) Pp. 191-345+15 plates. (Køb havn: Andr. Fred. Høst og Søn, 1923.) Kr. 21.2

As a result of more than twenty years' careful systematic observations carried out on the Rotifers numerous ponds in North and Middle Iceland, author of this important monograph has added grea to our knowledge of a very puzzling group of anim It was Ehrenberg who first clearly separated Rotifera from the Protozoa, with which they h previously been associated on account of their mic scopic size and general appearance, but he made serious error of regarding them as hermaphrodite, a it was not until 1848 that a male Rotifer was recogni as such by Brightwell. It is still commonly suppo that the males are very scarce, and until the appe ance of the work under review, males had been fou in little more than 100 out of the 1000 known spec This apparent scarcity is now shown to be due v largely to the fact that males are produced only certain periods of the year, but they may then app in enormous numbers. The ordinary method of production is by means of parthenogenetic eggs, l periodically, in some species once, in others tw a year—and only under favourable conditions— enormous increase in numbers takes place, and t "maximum" heralds the appearance of the ma from special male-producing eggs. They live only a few days at most and then disappear completely a almost simultaneously. The fertilised females prod the well-known "resting eggs," which always give r to females and inaugurate a new period of parthe genesis. The males of many species are still unkno but it seems probable that all give rise to males un suitable conditions.

It is interesting to observe that the author agr with de Beauchamp in considering the Rotifera to most nearly allied to the Turbellaria.

The work is accompanied by fifteen plates of excell figures, and the author is to be congratulated ve heartily on his interesting and valuable results.

Die Kolloidchemie als Hilfswissenschaft der Mineralo und Lagerstättenlehre und ihre Anwendung auf metasomatischen Blei-Zink-Lagerstätten. Von Dr. Bernauer. Pp. viii+83. (Berlin: Gebrüder Bo traeger, 1924.) 5*s*.

THE original object of this small work, as stated in t preface, was to inquire what part colloidal process and more particularly gel formation, played in me somatosis. Although the conception that ma minerals were gels had been systematically develop by Cornu, and had been adopted by Doelter and l collaborators, the author states that he could not fi anywhere a synopsis of the properties of mineral ge and therefore devotes the first part of the book to description of their characteristics and to the metho of diagnosis. The definition of a simple gel prepar *in vitro* is not easy, and does not become more so in t

ge of systems which may have undergone secondary transformations like re-crystallisation, so that diagnosis must rest on the simultaneous occurrence of a number of criteria. Due attention is given to a number of secondary phenomena, like fissures due to shrinkage, accidental double refraction, the influence of gels on crystal habitus, etc., which cumulatively point to a mineral having at some time passed through a gel stage.

The second part is devoted to the description and detailed investigation of metasomatic zinc-lead deposits, more particularly the well-known Wiesloch deposit, with especial attention to schalenblende and galena. Only the briefest summary of the author's conclusions is possible: he distinguishes three types of zinc sulphide, for at least two of which a gel may have been the original material, and three types of galena. The latter is always crystalline and the difference is one of habitus, which the author assumes to have been determined chiefly by the ratio of lead sulphide to zinc sulphide.

The book is an interesting example of the growing number of attempts to apply the results of colloid chemistry to the elucidation of natural phenomena, the direct imitation of which is unfortunately precluded chiefly by the time factor.

Kant's Treatment of Causality. By Dr. A. C. Ewing. Pp. viii + 243. (London: Kegan Paul and Co., Ltd., 1924.) 10*s.* 6*d.* net.
